Abstract

Keywords

- upper extremity
- artery
- angiography

Catheter arteriography of the upper extremity has become an infrequent procedure in modern practice given the advancements in computed tomography/magnetic resonance angiography (CT/MRA). However, catheter angiography continues to have major diagnostic and interventional roles in certain pathophysiologic conditions. This article discusses the indications and techniques of upper extremity catheter angiography, and presents classic cases to demonstrate key anatomic, diagnostic, and interventional considerations.

Introduction

Catheter angiography remained the gold standard for evaluation of upper extremity arterial pathology until succeeded by computed tomography angiography¹ (CTA) and magnetic resonance angiography (MRA). Although its scope has narrowed, it continues to play an important role in the evaluation and management of trauma, limb ischemia, hemodialysis access, vasculitis, and vascular anomalies.

Herein we review the modern indications of upper extremity catheter angiography, patient preparation and angiographic techniques, normal and variant anatomy, and classic angiographic diagnoses.

Indications

Trauma

Evaluation of upper extremity injury begins with rapid physical examination to assess for signs of major arterial injury, such as expanding hematoma, pulsatile bleeding, palpable thrill or audible bruit, and profound distal ischemia.² Evaluation for injuries not definitive on physical examination may involve Doppler ultrasound and/or CTA. Catheter angiography is a useful problem-solving tool when CTA is inconclusive. Furthermore, suspicious findings on the noninvasive imaging may prompt angiography for operative planning or definitive endovascular intervention.

Common traumatic arterial injuries include pseudoaneurysm, dissection, thrombosis, transection, and arteriovenous fistula (►Figs. 1–3), and may occasionally be amenable to endovascular treatment. In a small retrospective study, Carrafiello et al reported high technical success and short-term clinical success rates for treating pseudoaneurysms and transections with stent grafts and treating dissections and mural hematomas with bare stents or angioplasty.³ Long-term patency rates in this setting are not well established. Endovascular intervention for upper extremity trauma is rare in clinical practice, and surgical management remains standard of care especially in penetrating trauma.

Acute Limb Ischemia

Acute limb ischemia presents with varying degrees of severity (►Table 1), ranging from a viable limb with intact sensorimotor functions to an irreversible ischemic damage with profound sensorimotor deficits.⁴ Those presenting with severe acute ischemia (i.e., Rutherford category IIb or III) should undergo emergent surgical revascularization or amputation.

Catheter-directed thrombolysis for acute thromboembolism in the upper extremity is an attractive alternative to surgical embolectomy in patients without immediate threat of limb loss.^{5,6} These cases typically include patients with Rutherford category I and IIa acute ischemia.^{4,7} Common clinical situations include distal embolism from the

Fig. 1 Brachial artery traumatic occlusion. An avulsion injury was sustained during waterskiing, and the patient presented with diminished peripheral left upper extremity pulses. Emergent angiographic evaluation revealed occlusion of the proximal brachial artery (curved arrow). Robust profunda brachii branches are visualized (straight arrow).

Fig. 2 Penetrating trauma arterial injuries. (A) Gunshot wound to the hand resulting in pseudoaneurysm and transection of the deep palmar arch (arrow). Multiple surgical fixation wires are noted. (B) Brachial arteriogram after penetrating trauma to the upper extremity demonstrates a patent brachial artery (arrow) and profunda brachii muscular branch (dashed arrow). (C) While a discrete arteriovenous connection was not identified, a dilated early draining cephalic vein (arrow) in the territory of the muscular branches suggested shunting through small traumatic fistulas.

Fig. 3 Iatrogenic trauma—arteriovenous fistula postradial artery access. (A) Radial artery angiogram demonstrates a fistulous connection between the radial artery and cephalic vein (arrowhead). (B) Ulnar artery angiogram injection confirms the previous finding with steal phenomenon through the palmar arch.

Table 1 Rutherford classification for acute limb ischemia⁴

Category	Description/Prognosis	Findings		Doppler signal	
		Sensory deficit	Motor deficit	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	None or minimal	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	Mild or moderate	Mild or moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound (anesthetic)	Profound (paralysis)	Inaudible	Inaudible

subclavian artery injury in the setting of arterial thoracic outlet syndrome (►Fig. 4) and cardiogenic thromboembolism (►Fig. 5). Standard absolute and relative contraindications to pharmacologic thrombolysis apply (►Table 2).⁸ An infusion catheter is positioned across or just proximal to the site of occlusion, with an initial bolus of 3 to 5 mg t-PA, followed by infusion at 0.5 to 1 mg/h. Systemic heparin can be concomitantly administered through the arterial sheath for a goal activated partial thromboplastin time (aPTT) of 60 to 80 seconds. Compared with lower extremity thrombolysis, risks

are considerable and include distal embolization of loss of digits and brachial sheath hematoma with neurologic injury; thrombolysis is best considered in an interdisciplinary fashion and weighed against the feasibility and risks of surgical embolectomy or conservative management with anticoagulation alone. Patients undergoing thrombolysis are monitored in the intensive care unit for clinical improvement and hemorrhagic complications. Repeat angiography after 12 to 24 hours of thrombolysis assesses for restoration of flow and presence of an underlying lesion.

Fig. 4 Arterial thoracic outlet syndrome. **(A)** Left subclavian arteriogram demonstrates aneurysmal dilation and irregular filling defects at the distal subclavian artery (arrow). The proximal brachial artery (asterisk) is occluded from a large embolus. **(B)** Overnight catheter-directed thrombolysis using tPA infusion restored brachial arterial flow. **(C)** Repeat subclavian arteriogram with arm abduction accentuates the arterial compression. Poststenotic dilation (dashed arrow) is typical of arterial thoracic outlet syndrome.

Fig. 5 Cardiac embolism in atrial fibrillation. **(A)** Selective radial arteriogram demonstrates occlusion at the radiocarpal joint (arrow) due to embolus in a patient with atrial fibrillation. **(B)** Hand arteriogram demonstrates preserved ulnar arterial flow (arrowhead) with complete superficial palmar arch that supplies all the digits. **(C)** Repeat hand arteriogram after catheter-directed thrombolysis demonstrates restored flow in the radial artery (dashed arrow).

Bypass Graft Planning

The radial artery is a frequently used arterial conduit for coronary artery bypass surgery⁹ and extracranial-intracranial bypass surgery. Upper extremity catheter angiography is often performed in conjunction with coronary or carotid angiography to assess the safety and suitability of arterial harvest (→ Fig. 6).

Table 2 Contraindications to pharmacologic thrombolysis⁸

Absolute
- Established cerebrovascular event (including TIAs) within past 2 mo
- Active bleeding diathesis
- Gastrointestinal bleeding within past 10 d
- Neurosurgery (intracranial, spinal) within past 3 mo
- Intracranial trauma within past 3 mo
Relative
- Cardiopulmonary resuscitation within past 10 d
- Major nonvascular surgery or trauma within past 10 d
- Uncontrolled hypertension: systolic > 180 mm Hg or diastolic > 110 mm Hg
- Puncture of noncompressible vessel
- Intracranial tumor
- Recent eye surgery

Abbreviation: TIA, transient ischemic attack.

Fig. 6 Preoperative catheter angiography for radial artery harvesting. **(A)** Angiographic Allen's test. Clamp compression of the radial artery confirms complete deep palmar arch (arrow) filling from the ulnar artery. This radial artery can be safely ligated and harvested. **(B)** Angiography in a second patient demonstrates segmental occlusion of the distal radial artery (arrowhead), asymptomatic and attributed to prior arterial line access. Note the complete superficial palmar arch from the ulnar artery (arrow).

Dialysis Access Steal Syndrome

Symptomatic hand ischemia in patients with dialysis access ("steal syndrome") is an infrequent but serious condition. Signs and symptoms include paresthesia, weakened pulses, pain, muscle atrophy, paralysis, decreased skin temperature, cyanosis, and gangrene. Multiple coexisting etiologies, including retrograde flow distal to the anastomosis, arterial inflow stenosis, and distal arteriopathy, contribute.¹⁰ When suspected, the workup begins with Doppler ultrasound. For severe symptoms or digital

pressures lower than 50 mm Hg,¹¹ catheter angiography can confirm reversal of flow (►Fig. 7), distal arteriopathy, and/or presence of inflow stenosis.

Fig. 7 Dialysis access steal phenomenon. (A) Brachial arteriogram demonstrates early branching of the radial (asterisk) and ulnar arteries (arrowhead). (B) Dialysis arteriovenous loop graft (curved arrow) is anastomosed with the radial artery. The graft is widely patent. There is antegrade flow in the ulnar artery (arrows denote direction of flow). No antegrade flow is seen along the radial artery. (C) The ulnar artery retrogradely supplies the radial artery via the deep palmar arch (dashed arrow), confirming true steal physiology.

Vasculitis

Laboratory analysis typically precedes imaging for suspected vasculitis. While the presence and concentrations of certain serologic markers may have adequate specificity for diagnosis, angiography is often a helpful adjunctive method. While high-quality CTA/MRA are often adequate to evaluate medium- and large-vessel vasculitides, small-vessel vasculitides (e.g., microscopic polyangiitis, granulomatosis with polyangiitis, Churg-Strauss syndrome) are better assessed with the superior spatial resolution of catheter angiography.¹²

Vascular Anomalies

Catheter angiography is considered when CTA or MRA fails to adequately demonstrate arterial feeder(s) of arteriovenous fistulas and malformations. It can clarify the anatomy of the lesion prior to endovascular embolization or surgery (►Fig. 8). Angiography also plays an important role in preoperative embolization of vascular tumors involving the upper extremity, such as sarcomas and hypervascular metastases, with intention to decrease operative blood loss.

Techniques

Preparation and Patient Positioning

Equipment must be able to accommodate imaging of the entire upper extremity (aortic arch to fingertips). For suspected

Fig. 8 Arteriovenous malformation. (A) Time-resolved magnetic resonance angiography image of the right hand demonstrates an arteriovenous malformation at the ulnar aspect of the wrist. (B) Angiogram confirms the previous finding with excellent spatial detail confirming complex supply from radial, ulnar, interosseous, and arch arteries.

vasculitis, catheter angiography of the clinically unaffected upper extremity, lower extremities, and mesenteric arteries should be considered to confirm and evaluate systemic involvement. For compression syndromes (discussed below), patient positioning should allow for provocative maneuvers without disrupting the sterile barrier.

The arterial vasculature of the hand is highly sensitive to various stimuli commonly found in the angiography suite, including cold temperature, pressure/restraints, pain, and anxiety.¹³ These should be eliminated or mitigated with heat packs, warm blankets, sedation, and careful positioning to avoid false-positive examinations.

Patient cooperation and comfort minimize motion artifacts. Position the hand flat on a padded arm board in anatomic position (i.e., palm up) with the digits slightly spread out to avoid overlapping vessels. Tight restraints or heavy hot packs should be avoided to minimize direct pressure on the arteries.

Equipment and Access

The arch aortogram is performed via a pigtail flush catheter in a 30-degree left anterior oblique projection (i.e., “candy cane” view), at a 15- to 30-mL/s injection rate for a total of 30 to 50 mL of contrast agent, and with at least three to four frames per second imaging acquisition. A 100- to 125-cm, 4 or 5F angled catheter (e.g., Vertebral, Berenstein, or Headhunter) is used to select the target subclavian artery (►Fig. 9). In cases of tortuous and ectatic arches, reverse curve catheters (e.g., Simmons) may be useful. The subclavian arteriography is performed in the anteroposterior (AP) projection, typically at a 5- to 7-mL/s injection rate for a total of 10 to 15 mL of contrast agent, and with two frames per seconds imaging acquisition. Arteriography of the remaining upper extremity is performed in multiple stations. Further selection of the brachial artery may improve image quality and reduce contrast bolus volumes. Decreased frame rate (e.g., one to two frames per seconds) reduces radiation in the setting of diseased distal arteries with slow flow.

Fig. 9 Right subclavian artery catheterization technique. A vertebral catheter is advanced into the ascending aorta with the curve of the catheter matching the aorta. The catheter is turned counter-clockwise for cephalad orientation of the catheter tip and slowly withdrawn until the brachiocephalic artery is selected. The catheter is then turned clockwise while being slowly advanced during gentle manual contrast injection until the right subclavian artery is selected.

Vasodilators

Available agents for prevention and reversal of vasospasm include nifedipine (10 mg SL or PO), verapamil (2.5–5 mg intra-arterial), nitroglycerine (100–200 µg intraarterial or 1–2 in [7.5–15 mg] transdermal paste), papaverine (60 mg intra-arterial), and tolazoline (25 mg intra-arterial). Agents may be combined for maximum result, while closely monitoring the systemic blood pressure.

Diagnosis

Anatomy and Variants

The aortic arch conventionally gives rise to the brachiocephalic artery, left common carotid artery, and left subclavian artery (►Fig. 10). Arch variations occur in approximately 17%, most frequently a common origin of the brachiocephalic and left common carotid arteries (15%).¹⁴

The brachiocephalic artery gives rise to the right subclavian artery and the right common carotid artery. The subclavian artery extends to the lateral border of the first rib, where it continues as the axillary artery (►Fig. 11). Branch patterns of the subclavian artery are variable, but they include the vertebral artery, internal thoracic artery, thyrocervical trunk, and costocervical trunk. The axillary artery extends from the lateral border of the first rib to the lateral border of the teres minor muscle. The major branches of the axillary artery include thoracoacromial, lateral thoracic, subscapular, and circumflex humeral arteries. The axillary artery continues as the brachial artery in the upper extremity (►Fig. 11). The profunda brachii is the largest branch of the brachial artery, supplying muscular branches to the posterior upper arm. Collateral pathways at the elbow are named for their anastomotic connections (e.g., radial and ulnar recurrent arteries). The brachial artery terminally divides into the ulnar and radial arteries within the inferior aspect of the cubital fossa (►Fig. 12). The ulnar artery gives rise proximally to the interosseous artery.

Fig. 10 Aortic arch anatomy. (A) Conventional aortic arch. There are three distinct origins of the great vessels, including the brachiocephalic (innominate) artery (1), left common carotid artery (2), and left subclavian artery (3). (B) Bovine aortic arch. This is the most common variant of the arch with a common truncus (4) for the brachiocephalic (1) and left common carotid (2) arteries. The left subclavian artery origin remains separate.

Fig. 11 Subclavian, axillary, and brachial artery conventional anatomy. (A) The subclavian artery (1) gives off the vertebral artery (3), internal thoracic artery (4), and thyrocervical trunk (5). The axillary artery (2) gives off the thoraco-acromial (6), lateral thoracic (7), subscapular (8), circumflex scapular and thoracodorsal branches, and circumflex humeral arteries (9). (B) The brachial artery (10) gives off profunda brachii (11) before bifurcating near the elbow into the radial (12) and ulnar (13) arteries.

Fig. 13 Brachial artery variant anatomy. (A) High origin of the radial artery (arrowhead) from the brachial artery (asterisk) in the upper arm. (B) High origin of the ulnar artery (arrow) from the brachial artery (asterisk) in the upper arm. Note the multifocal narrowing and irregularity of the ulnar and radial arteries in this patient with traumatic humeral fracture resulting in diffuse stretch injury and vasospasm. (C) Persistent median artery (curved arrow) supplying significant flow to the hand. Normal radial artery (arrowhead) is seen, whereas the ulnar artery (arrow) is diminutive.

Common anatomic variants of the arm and forearm arteries include early origin of the radial or ulnar arteries (►Fig. 13A, B). This so-called high origin of the radial artery is relatively common, occurring in up to 14% of patients, while a high origin of the ulnar artery is much less frequent, occurring in 0.17 to 2%.^{15,16} Continuation of the interosseous artery as a distinct third vessel entering the hand, termed a persistent median artery (►Fig. 13C) is rare and may cause compressive neuropathy involving the median nerve.¹⁷

Arterial supply to the hand consists of multiple complex anastomotic networks in the palmar and dorsal aspects of

Fig. 12 Forearm artery conventional anatomy. (A) The distal brachial artery (1) bifurcates at the inferior aspect of the cubital fossa into the ulnar (2) and radial (3) arteries. The ulnar artery characteristically gives rise to the interosseous artery (4). (B) The ulnar and radial arteries course along the forearm and enter the hand.

Fig. 14 Hand artery conventional anatomy. Native (A) and digital subtraction (B) angiograms of the hand. The radial artery supplies the deep palmar arch (1), and the ulnar artery supplies the superficial palmar arch (2). At the level of the mid metacarpals, the superficial palmar arch gives rise to common palmar digital arteries (3), which are joined by palmar metacarpal arteries (4) originating from the deep palmar arch. At the web space, the common palmar digital artery splits into two proper palmar digital arteries (5) to supply the adjacent fingers. (C) Hand angiogram in another patient. Note the diminutive and nearly incomplete superficial palmar arch (2) compared with the distinct deep palmar arch (1).

the hand, formed by branches of the ulnar and radial arteries (►Fig. 14). The palmar component is based on two palmar arches: superficial (distal and supplied by the ulnar artery) and deep (proximal and supplied by the radial artery). These arches are frequently incomplete, particularly the superficial palmar arch where a true arcade is only present in one-third of cases (►Fig. 14B).¹⁸ The superficial palmar arch gives rise to the common palmar digital arteries, which join the palmar metacarpal arteries originating from the deep palmar arch. At the web space, the common palmar digital artery splits into two proper palmar digital arteries to supply the adjacent fingers.

Classic Angiographic Cases

Takayasu's Arteritis

Takayasu's arteritis is a large-vessel vasculitis commonly affecting the aorta and its branch vessels and frequently occurs in young women of Southeast Asian and Indian descent.¹⁹ Smoothly tapering stenoses or complete occlusions involving major aortic branch vessels are typical (►Fig. 15), frequently with extensive collateralization if long standing. Aneurysms are infrequent.

Fig. 15 Takayasu's arteritis. An 8-year-old female with diminished peripheral left upper extremity pulses. **(A)** LAO arch aortogram. There is smooth stenosis of the posterior aortic arch (arrow) with occlusion of the left common carotid and proximal left subclavian arteries. The brachiocephalic artery (arrowhead) is relatively preserved and serves as the only intracranial inflow. The distal subclavian artery is faintly noted (curved arrow). **(B)** Delayed image from brachiocephalic arteriogram. The distal left subclavian artery (curved arrow) and internal thoracic artery (asterisk) are supplied by the retrograde flow through the left vertebral artery (dashed arrow).

Arterial Thoracic Outlet Syndrome

The spectrum of symptomatic thoracic outlet syndrome includes neurogenic, venous, and arterial manifestations, of which arterial is least common. Mechanical compression by adjacent musculoskeletal structures such as a cervical rib, the clavicle, or the scalene musculature results in repetitive microtrauma to the subclavian or axillary artery, typically becoming evident with acute or chronic limb ischemia. A bruit over the subclavian artery may be found on physical examination, along with diminished ipsilateral pulses. Angiographic findings include extrinsic compression, aneurysm, dissection, in situ thrombosis, focal stenosis, poststenotic dilation, and distal embolism. Provocation with positional maneuvers during angiography, typically arm hyperabduction and external rotation with or without contralateral head rotation, confirms the diagnosis (►Fig. 4).

Thromboangiitis Obliterans (Buerger's Disease)

Thromboangiitis obliterans (Buerger's disease) is a small- to medium-vessel non-necrotizing vasculitis, typically involving the peripheral arteries and veins of the distal upper and lower extremities. This disease most commonly affects young men with a history of smoking. Clinical presentation ranges from claudication to ischemic ulceration. Angiographic findings include extensive distal arterial occlusions classically with "corkscrew" collaterals representing the dilated vasa vasorum (►Fig. 16). Proximal large inflow vessels are preserved.

Hypothenar Hammer Syndrome

Repetitive blunt or vibratory trauma to the palm (e.g., jack-hammer workers, karate enthusiasts) can cause arterial injury to the ulnar artery as it crosses the hook of hamate, with

Fig. 16 Thromboangiitis obliterans (Buerger's disease). **(A)** Spared forearm inflow arteries. The distal brachial artery (arrow) and proximal to midradial (arrowhead) and ulnar (curved arrow) arteries are normal. The distal radial and ulnar arteries, however, demonstrate the classic "corkscrew" collaterals. **(B)** There is diffuse occlusion of the named arteries of the hand with extensive collateralization and poor perfusion of the digits. **(C)** Lower extremities are often involved as well. Multiple "corkscrew" collaterals are seen in the anterior tibial artery (arrow) and posterior tibial artery (arrowhead) territories. **(D)** Hand angiogram of a different patient demonstrates occlusion of the ulnar artery (asterisk), numerous tortuous collaterals within the palm, and proper digital artery occlusions in multiple fingers (arrowheads). The radial artery (arrow) is relatively preserved.

Fig. 17 Hypothenar hammer syndrome. **(A)** The ulnar artery is occluded (arrowhead), whereas the radial artery (arrow) is intact. Multiple microaneurysms (curved arrow) are seen over the hamate. **(B)** Distal occlusions of the proper digital arteries (arrows) are noted in the fourth digit.

resultant digital ischemia ("hypothenar hammer syndrome"). Angiographic findings include ulnar artery occlusion, aneurysm formation, and distal embolism (►Fig. 17).

Raynaud's Phenomenon

Raynaud's phenomenon consists of episodic symptomatic attacks of distal small vessel vasospasm in the hands, precipitated by stimuli such as exposure to cold. Sharply demarcated skin color changes of the digits are classic. Digits initially appear white and progress to blue (a manifestation of stagnated deoxyhemoglobin), then red (reactive hyperemia), before returning to normal.²⁰ Raynaud's phenomenon may be primary or secondary to a systemic collagen vascular process, such as lupus, Sjögren's syndrome, or scleroderma. Angiographic findings range from completely normal between episodes of vasospasm to digital artery occlusions and hypoperfusion of the finger tips during exacerbations (►Fig. 18).

Fig. 18 Raynaud's phenomenon. Hand angiography in a patient with Raynaud's syndrome demonstrates hypoperfusion of the finger tips (arrowheads) but with relatively normal-appearing proximal vessels.

Conclusion

Although infrequently performed, catheter angiography of the upper extremity remains essential in specific clinical scenarios. Familiarity with normal and variant anatomy, basic angiographic techniques, and classic appearances of certain pathologic entities will prove useful when the need for this procedure arises.
