Abstract

Background Endotracheal intubation is a skill required for resuscitation. Due to various reasons, intubation opportunities are decreasing for health care providers.

Objective To compare the success rate of video laryngoscopy (VL) and direct laryngoscopy (DL) for interprofessional neonatal intubation skills in a simulated setting.

Methods This was a prospective nonrandomized simulation crossover trial. Twenty-six participants were divided into three groups based on their frequency of intubation. Group 1 included pediatric residents; group 2 respiratory therapists and transport nurses; and group 3 neonatal nurse practitioners and physicians working in neonatology. We compared intubation success rate, intubation time, and laryngoscope preference.

Results Success rates were 100% for both DL and VL in groups 1 and 2, and 88.9% for DL and 100% for VL in group 3. Median intubation times for DL and VL were 22 seconds (interquartile range [IQR] 14.3–22.8 seconds) and 12.5 seconds (IQR 10.3–38.8 seconds) in group 1 ($p = 0.779$); 17 seconds (IQR 8–21 seconds) and 12 seconds (IQR 9–16.5 seconds) in group 2 ($p = 0.476$); and 11 seconds (IQR 7.5–15.5 seconds) and 15 seconds (IQR 11.5–36 seconds) in group 3 ($p = 0.024$).

Conclusion We conclude that novice providers tend to perform better with VL, while more experienced providers perform better with DL. In this era of decreased clinical training opportunities, VL may serve as a useful tool to teach residents and other novice health care providers.

Endotracheal intubation is an imperative skill for resuscitation in a critical care setting. Due to the increased use of noninvasive ventilation,¹ changes in recommendations for intubating meconium-stained infants,^{2,3} and presence of multiple health care providers, the opportunities for residents and other health care professionals to practice intubation in real-life situations are decreasing. All of these factors are contributing to a low intubation success rate. As a result, residents do

not have adequate opportunities to achieve competence.⁴ Multiple failed intubation attempts may actually contribute to decreased success rate.⁵

Intubations by inexperienced personnel may require an increased number of intubation attempts associated with adverse events. A multicenter observational cohort study in pediatric intensive care units identified that pediatric residents require extensive training before intubating real

patients.⁶ Refresher training sessions improve intubation success rate in both inexperienced and experienced health professionals.⁷ Repeated procedural simulation workshops boost residents' confidence and competence, regardless of the year of training.^{8,9}

For decades, direct laryngoscopy (DL) has been considered the gold standard for intubation. Video laryngoscopy (VL) is an indirect laryngoscopy when a magnified view of the airway is displayed on a monitor. It has been associated with a higher success rate with nonexpert trainees and difficult airway situations.^{10,11} Improved intubation success rates may be explained by simultaneous feedback from instructors who share the video laryngoscope screen with the learner.¹²

There are controversial data among studies focused on the role of VL in training residents and other nonexpert trainees. At the same time, the role of VL in assessment and maintenance of skills by trained health care professionals remains unclear.

The purpose of this study was to compare the success rates of intubation by video and direct laryngoscopes among professionals with different level of experience in a simulated setting in order to find the preferred method for training residents and maintenance of skills by other health care professionals, with the aim of including it in a simulation curriculum subsequently.

Methods

Study Design

We conducted a nonrandomized crossover trial in simulation to compare intubation experience with direct and video laryngoscopes (GlideScope) at the Royal University Hospital, Saskatoon in March 2017. The study had been approved as exempt from review by the University of Saskatchewan Research Ethics Board in August 2016 and by the Johns Hopkins University Homewood Institutional Review Board in January 2017. Oral consent was obtained from all participants.

Equipment and Materials

The devices used for the study were a direct laryngoscope and GlideScope video laryngoscope. Miller size 1 blade and GVL1 single use STAT were used for intubation with direct and video laryngoscopes, respectively. All intubations were performed using an endotracheal tube with an internal diameter of 3.5 mm and a stylet. The endotracheal tubes were lubricated before the procedure. The manikin used for the study was SimNewB by Laerdal. A self-inflating bag and stethoscope were used to confirm placement.

Participants

Twenty-six participants working in neonatal intensive care unit at the Royal University Hospital, Saskatoon were recruited. Participants were divided into three groups based on the frequency of intubation: (1) residents (low frequency); (2) transport nurses and respiratory therapists (medium frequency); and (3) neonatal nurse practitioners and physicians (high frequency). There were eight, nine, and nine participants in groups 1, 2, and 3, respectively (►Fig. 1). The demographic characteristics of participants are described in ►Table 1.

Procedures

The participants watched a short video on the use of GlideScope. They received a brief demonstration by one of the investigators on the use of both laryngoscopes on manikin. They were not allowed to practice before recruitment. The participants were asked to intubate with direct and video laryngoscopes in a nonrandom sequence. There were two data collection instruments; one was the data collection sheet that was filled in by the observer as the participants performed the procedure. The observer used a stopwatch to measure the time taken for successful intubation. The second instrument was the survey questionnaire given to participants after the study. The data recorded included successful first attempt intubation, intubation time, number of attempts, laryngoscope preference, self-reported confidence, years of experience, recent life support training, etc. Both instruments were developed after reviewing literature on crossover studies comparing the two kinds of laryngoscopes. The data collection instruments were finalized after the authors reached a consensus. There were only two individuals who observed the participants and most of the times both were present, only one observer recorded the data.

Outcomes

The primary outcome of the study was successful first attempt intubation that was defined as correct tube placement confirmed by chest rise and auscultation. The secondary outcomes included intubation time (in seconds, from the time of insertion of laryngoscope blade into the manikin's mouth to its removal) and laryngoscope preference for learning.

Statistical Analysis

The data were compiled and recorded on a Microsoft Excel spreadsheet and analyzed by the Statistical Package for Social Sciences (SPSS) v23 for Windows. Effect size was calculated through Microsoft Excel. Wilcoxon's signed rank test was used to analyze the time to intubation. Successful first attempt intubation and number of attempts were reported as numbers and percentages. A chi-square test was used to analyze the laryngoscope preference. A p -value of ≤ 0.05 was considered significant. Results were presented as medians, interquartile range (IQR), numbers, and percentages as the data were not normally distributed.

Results

Successful First Attempt Intubation

All participants were able to intubate successfully with both laryngoscopes in first attempt except one in group 3, who required three attempts with the direct laryngoscope and one with the video laryngoscope (►Table 2).

Intubation Time in Seconds

Group 1 residents: Intubation time was longer with direct laryngoscope as compared with the video laryngoscope, although this difference was not statistically significant ($p = 0.779$), with an effect size of 0.1 (►Table 3, ►Fig. 2). The median time was 22 seconds (IQR 14.3–22.8 seconds) in the direct arm and 12.5 seconds (IQR 10.3–38.8 seconds) in

Fig. 1 Flow chart of recruitment and design based on CONSORT statement. DL, direct laryngoscopy; VL, video laryngoscopy.

the video arm. Two participants took longer than 30 seconds to intubate with the video laryngoscope.

Group 2 respiratory therapists (RTs) and registered nurses (RNs): Intubation time was longer with the direct laryngoscope than with the video laryngoscope, this difference was not statistically significant ($p = 0.476$) with an effect size of 0.36 (►Table 3, ►Fig. 2). The median time was 17 seconds (IQR 8–21 seconds) in the direct arm and 12 seconds (IQR 9–16.5 seconds) in the video arm. All participants intubated in < 30 seconds with both laryngoscopes.

Group 3 physicians (MDs) and neonatal nurse practitioners (NNPs): Intubation time was significantly shorter with the direct laryngoscope when compared with the video laryngoscope ($p = 0.024$) with an effect size of 1.25 (►Table 3, ►Fig. 2). The median time was 11 seconds (IQR 17.5–15.5 seconds) in the direct arm and 15 seconds (IQR 11.5–36 seconds) in the video arm. All participants intubated with the direct laryngoscope in < 30 seconds, while two took longer than 30 seconds with the video laryngoscope (only successful attempts were included for this analysis).

Laryngoscope Preference

Group 1: Six out of eight participants (75%) preferred VL for learning ($p = 0.044$) (►Table 4, ►Fig. 3).

Group 2: Six out of eight (66.7%) chose VL for learning, although the difference was not statistically significant ($p = 0.097$) (►Table 4, ►Fig. 3).

Group 3: Five out of nine participants (55.6%) preferred both laryngoscopes for learning ($p = 0.739$) (►Table 4, ►Fig. 3).

Discussion

The opportunities for neonatal intubation for pediatric trainees have reduced significantly over the years with a similar effect on the success rate.⁴ A retrospective study of critical procedures performed in pediatric emergency department showed that if clinical experience is the exclusive source of learning, then fellows' achievement of competence is questionable along with increased risk of skill decline in faculty.¹³

Current data about VL and DL as teaching tools for successful intubation in simulation setting are controversial. According to a systematic review, nonexpert users had faster intubation time and a better success rate with a video laryngoscope.¹⁰ A meta-analysis showed that time to intubation is longer with VL when compared with DL.¹⁴ On the contrary, a randomized trial comparing the DL and VL for difficult airways by expert intubators showed that VL

improves the success rate and shortens the intubation time.¹⁵

In our study, we found out that more experienced providers had the shortest intubation time with the direct laryngoscope, while providers with limited experience showed a tendency toward faster intubation with the video laryngoscope. The median time for successful intubation among residents was almost two times faster with VL as compared with DL that supports the idea that additional visual tool (monitor with magnified view) helps acquisition of new skill (intubation).¹⁶ For the experienced intubators, the absolute difference between intubation times with two different laryngoscopes was not remarkable but still remained significant (11 seconds for DL vs. 15 seconds for VL). The fact that intubation time with VL for this group was the longest among all participants could be explained with interference of already acquired skills (muscular memory) and the need to implement additional visual tool (monitor).

Our other finding was that novice or less experienced providers preferred video laryngoscope for learning. The participants reported that it allowed for a better visualization, guided learning with feedback, and enhanced self-confidence. Some participants chose both laryngoscopes based on their unique features; VL can be used for difficult airways and DL still remains the standard of care and can be used in situations where video laryngoscope is not available. The learners' preference of VL could be explained with a better glottic view in children¹⁷ and opportunity to have magnified view on the screen shared by instructor and learner.¹⁸ A simulated randomized crossover trial showed that novice providers have a higher intubation success rate after receiving video-assisted instruction when compared with traditional instruction.¹⁹ Another randomized trial, in real patients, demonstrated the highest intubation success rates achieved in novice neonatal intubators when the instructor shared the same video laryngoscope screen.¹²

We did not assess for retention of skills in this group, but another study has shown that pediatric residents were able to maintain their success rates with DL after being taught through VL.¹¹

There are a few limitations to this study. The sample size was relatively small; generalizability to a bigger or a different population may not reproduce the same results. Although some participants may represent providers at other institutions such as residents and attending physicians, some members may be unique to this group, that is, transport nurses and respiratory therapists who do not routinely intubate in many centers. Only one type of video laryngoscope was used in this study; the results may be different with other video laryngoscopes.

Conclusion

In this era of decreased clinical training opportunities, video laryngoscope may serve as a useful tool to teach residents and other novice health care providers. It should be routinely used in simulation by expert health care providers for maintenance of skills and to familiarize them with the
