Abstract

Purpose The main purpose of this article is to assess the outcomes of endovascular management of pancreatitis-related hemorrhage.

Materials and Methods Retrospective analysis of patients referred for endovascular management of pancreatitis-related bleeding from January 2010 to December 2017 was performed. Patients' demographics, clinical presentation, etiology, laboratory findings, angiography findings, details of the endovascular procedure, technical outcome, clinical outcome, and complications were assessed.

Results One hundred and five patients with a mean age of 37 years were included in this study. Splenic artery (41.7%) was the most commonly involved vessel. Middle colic, left colic, superior mesenteric, jejunal, left inferior phrenic, and left renal subcapsular arteries were the less commonly involved vessels. Embolization was performed using coils in 72 (68.5%) patients, *n*-butyl cyanoacrylate (*n*-BCA) in 21 (20%) patients, both coil and *n*-BCA in 8 (7.6%) patients, and 4 (3.8%) patients underwent stent graft placement. Technical success was achieved in 98% (*n* = 103) and clinical success in 93.2% (*n* = 96) of patients. Rebleeding was seen in 6.8% (*n* = 7) of patients. Six patients with rebleeding were managed by reintervention. Four patients had rebleeding from the same vessel, and two patients had rebleeding from a different vessel. One patient died due to massive rebleeding. Minor complications were seen in 14.2% (*n* = 15), major complications were seen in 3.8% (*n* = 4), and mortality rate was 0.9% (*n* = 1).

Keywords

- hemorrhage
- pseudoaneurysm
- embolization

Conclusion Endovascular treatment is effective in the management of pancreatitis-related bleeding and is associated with low rebleeding rate and low mortality rate.

Introduction

Arterial hemorrhage is a rare complication of pancreatitis. The incidence of vascular complications in pancreatitis ranges from 1.2 to 15.2%. The vascular complications are more common in patients with chronic pancreatitis than acute pancreatitis with a reported frequency of 7 to 10% in patients

with chronic pancreatitis versus 1 to 6% in patients with acute pancreatitis.^{1,2} The most common vessels involved in pancreatitis-related pseudoaneurysm are the splenic artery in 30 to 50%, the gastroduodenal artery (GDA) in 20 to 25%, pancreaticoduodenal vessels in 20 to 25%, and mesenteric, colic, and hepatic vessels in the remaining patients.³ Mortality due to arterial hemorrhage in pancreatitis can be as

high as 34%.⁴⁻⁷ Mortality following surgical management of arterial hemorrhage varies from 20 to 50% with a rebleeding rate as high as 25%.⁷

Arterial hemorrhage in pancreatitis is multifactorial. In the presence of acute inflammation, the release of pancreatic enzymes leads to vessel wall weakening and erosions resulting in disruption of vessel wall and pseudoaneurysm. In pseudocysts and pancreatic collections, a combination of ischemic necrosis, infection, and the effect of the pancreatic enzymes causes vessel injury, pseudoaneurysm, and bleeding.⁵

Though endovascular management is the initial treatment option in most centers and is preferred over surgical management, the literature on the effectiveness of endovascular treatment is limited and the largest published data included only 37 patients.^{8,9} In this large population study, we report the safety and effectiveness of endovascular management in pancreatitis-related bleeding.

Material and Methods

This is a retrospective study of patients who had undergone endovascular management for pancreatitis-related bleeding at a tertiary care center. The data of all patients who received embolization or endovascular exclusion with stent grafts for pancreatitis-related bleeding between January 2010 to December 2017 were included. Ethical review was not required for this retrospective study. There were 105 patients (99 males and 6 females) with a mean age of 37 years (range: 7–73 years). Patients' demographics, clinical presentation, etiology, laboratory findings, angiography findings, details of endovascular procedure, technical outcome, clinical outcome, and complications were assessed. Computed tomography (CT) angiography was performed using a six slice multidetector CT scanner (Siemens Emotion) in all cases.

Angiography and Endovascular Management

Angiography were performed on a digital subtraction angiography system (Axiom Artis, Siemens). Angiography and endovascular interventions were performed through a right common femoral arterial approach in 104 patients and through a brachial artery approach in 1 patient. The celiac artery, superior mesenteric artery (SMA), and inferior mesenteric artery were catheterized and selective angiography performed. Super-selective catheterization of the common hepatic artery, GDA, left gastric artery, and splenic artery were performed either with a 4F catheter or a 3F microcatheter (Microferret, Cook Medical Inc.). The angiography images were reviewed for the presence of pseudoaneurysm, contrast extravasation, and vessel wall irregularity. The vascular abnormalities were treated either by embolization or by stent graft placement. Embolization was performed with coils of varying sizes (Cook Medical Inc.) or *n*-butyl cyanoacrylate (*n*-BCA) (Reevox Pharma) delivered through a 4F catheter for larger vessels or through a 3F microcatheter for smaller vessels. Coils were the preferred embolic materials, as coil embolization is technically easy, accurate, and

pseudoaneurysm can be excluded by proximal and distal coiling. Liquid embolic materials were preferred in pseudoaneurysm with difficult cannulation and in patient with multiple feeders. Stent graft was preferred in technically feasible end arteries to prevent ischemic complications. *n*-BCA was mixed with lipiodol (Guerbet) in the ratio of 1:1, 1:2, and 1:3 depending on the flow dynamics. For stent graft placement, the artery was catheterized, and access was secured with a stiff wire and a stent graft was deployed across the aneurysm or vascular abnormality. Angiography was repeated at the end of the procedure in all cases. The mean fluoroscopy time was 20 minutes (range: 15–60 minutes).

Outcomes

A technically successful embolization was defined as devascularization or cessation of blood flow to the target vascular bed. Technical success reflects immediate results and is evaluated at the completion angiography. Clinical success was defined as no rebleeding within 30 days of endovascular intervention and resolution of signs or symptoms that prompted the embolization procedure.¹⁰ Patients were monitored for immediate procedure-related complications like groin hematoma and pseudoaneurysm. Ultrasound was performed to assess for liver, splenic infarcts, and abscess. Clinical follow-up was done for any possible bowel ischemia.

Results

The demographics and clinical details of the patients are summarized in ►Table 1. Acute pancreatitis was seen in 37 patients and chronic pancreatitis in 68 patients. Abdominal pain was present in 74 patients, hematemesis in 35 patients, melena in 42 patients, hematochezia in 3 patients, and hemodynamic instability in 12 patients. The mean hemoglobin level was 8.3 g/dL.

Fifty-eight patients received blood transfusion: 21 patients received blood transfusion prior to embolization and 37 patients

Table 1 Patient demographics, etiology, clinical presentation, and laboratory findings

Number of patients	105
Male:female	99: 6
Mean age (range)	37 (7–73 years)
Etiology	
Acute pancreatitis	37 (35.2%)
Chronic pancreatitis	68 (64.7%)
Clinical presentation	
Pain abdomen	74
Hematemesis	35
Melena	42
Hematochezia	3
Hemodynamic instability	12
Mean hemoglobin	8.3 g/dL

following the embolization with a mean of 3.3 units of blood transfused per patient.

Conventional angiography was positive in 102 patients of which CT angiography was positive in 95 patients and negative in 7. Angiography demonstrated a pseudoaneurysm in 98 patients and contrast extravasation in 7 patients. This is compared with pseudoaneurysm in 89 patients and contrast extravasation in 6 patients on CT angiography. Both CT and conventional angiography were negative in three patients, and these three patients underwent empirical embolization of the GDA. Empirical embolization is therapeutic embolization of a vessel in which no active bleeding was identified.¹¹ Selection of artery for empirical embolization was based on both endoscopy findings and angiography findings such as the attenuated vessel and irregular margins of the artery. Arteries involved in the pancreatitis-related hemorrhage are summarized in ►Table 2.

Splenic artery was the most common involved vessel ($n = 48$) (►Fig. 1) followed by GDA ($n = 29$) (►Fig. 2). Left inferior phrenic artery ($n = 2$), left subcapsular renal artery ($n = 1$), and middle colic, left colic, and jejunal arteries (each $n = 1$) were the uncommon arteries involved.

Details of endovascular procedure and outcomes are detailed in ►Table 3. Embolization was performed in 101 patients. Coils were used in 72 patients (68.5%) (►Figs. 1–3), n -BCA in 21 patients (20%), and both coils and n -BCA in 8 patients (7.6%) (►Fig. 4). Stent graft was placed in four patients (3.8%) (►Fig. 5). Technical success was achieved in 103 (98.1%) patients. In two patients, immediate hemostasis was not achieved, and these two patients underwent surgical management. Clinical success was achieved in 96 of 103 patients (93.2%). Rebleeding was seen in seven patients (6.7%). Of these seven patients with rebleeding, six patients were managed by reintervention (four patients had bleeding from the same vessel that was treated, and two patients had bleeding from a different vessel). One patient died due to massive rebleeding.

Table 2 Arteries responsible for bleeding or pseudoaneurysm (based on angiography)

Artery	No. of cases (%)
Splenic artery	48 (45.2)
GDA	28 (25.6)
LGA	9 (8.2)
SMA	7 (6.4)
Celiac artery	1 (0.9)
IPDA	6 (5.5)
SPDA	2 (1.8)
CHA	2 (1.8)
RHA	2 (1.8)
Left inferior phrenic	2 (1.8)
Left renal artery	1 (0.9)
Middle, left colic, and jejunal artery	1 (0.9)

Abbreviations: CHA, common hepatic artery; GDA, gastroduodenal artery; IMA, inferior mesenteric artery; IPDA, inferior pancreaticoduodenal artery; LGA, left gastric artery; RHA, right hepatic artery; SMA, superior mesenteric artery; SPDA, superior pancreaticoduodenal artery.

Splenic infarct was seen in 18 (17.1%) patients, of which 15 were self-limiting. Splenic abscess and sepsis were observed in three patients. Two patients were managed conservatively, and one patient underwent splenectomy. One patient died from massive bleeding. The overall mortality rate was 1%.

Discussion

Arterial hemorrhage is a rare complication of pancreatitis. The incidence of arterial complications in pancreatitis can be as high as 15.2% with a mortality rate as high as 34%. The pathogenesis of arterial involvement is multifactorial and is due to destruction of vessel wall by the proteolytic enzymes released secondary to pancreatic inflammation and necrosis, and the combined effect of ischemic necrosis and proteolytic destruction of vessel wall in abscesses and pseudocysts.^{1–7}

Noninvasive evaluation of pancreatitis-related bleeding is usually performed with CT angiography. Conventional angiography is performed when CT angiography is positive, or when the bleeding persists despite a negative CT angiography. Conventional angiography has the advantage of real-time hemodynamic assessment of the vascular bed including the identification of the feeding vessel, collateral vessels, and concomitant therapeutic intervention.^{5,12,13} In the present study, conventional angiography was positive in 102 patients of which CT angiography was positive in 95 patients. Both CT and conventional angiography were negative in three patients and these three patients underwent empirical embolization.

The splenic artery was the most commonly involved vessel in our study. This has been previously reported in the literature.^{9,14,15} The less commonly involved vessels were left inferior phrenic artery (two patients), middle and left colic arteries (one patient), and left subcapsular renal artery (one patient). In literature, there are a few case reports of involvement of left renal artery, left inferior phrenic artery, and middle colic artery.^{9,15} Knowledge of involvement of uncommon vessels is important, as vascular abnormalities from these vessels can be missed and can lead to false negative angiography.

Arterial complications of pancreatitis are managed by embolization, stent graft placement, and surgery. Transarterial embolization has been considered as the initial treatment especially in hemodynamically stable patients.^{7,9,11,14,16} Surgery is reserved for patients with active bleeding, hemodynamically unstable patients, following failed embolization and for other secondary complications such as infection or extrinsic compression.^{7,16} Mortality rate following surgical management can range from 20 to 50%, depending upon the patient's hemodynamic state, the bleeding location, and timing of the surgery.⁷

The reported technical success ranged from 75 to 100% and clinical success ranged from 78 to 91.9%.^{9,14,15,17–21} The technical success in our study was 98.1% and clinical success was 93.2%. Coils were the preferred embolic materials. Coils were used in 72 (68.5%) patients and n -BCA in 21 (20%) patients and both in 8 (7.6%) patients. Most studies reported use of coils for embolization of pseudoaneurysms.^{9,11} This is expected given that the coils could be precisely deployed at the intended location and the chances of nontarget

Fig. 1 A 50-year-old male with chronic pancreatitis and pain abdomen. (A and B) Splenic angiogram shows distal splenic artery pseudoaneurysm. (C and D) Coil embolization of the pseudoaneurysm and distal splenic artery. (E) Postembolization angiography showed no filling of the pseudoaneurysm.

Fig. 2 A 40-year-old male patient with chronic pancreatitis and lower gastrointestinal bleeding. (A) Celiac and (B) hepatic angiography demonstrate a pseudoaneurysm of the gastroduodenal artery (GDA). Coil embolization of the GDA was performed. Postembolization (C) hepatic and (D) superior mesenteric artery angiography demonstrate no more filling of the pseudoaneurysm.

embolization would be low. A few studies have shown good outcomes with *n*-BCA.^{22,23} *n*-BCA is useful in patients with inaccessible arterial branches or aneurysms with multiple feeders or in patients with persistent aneurysm flow despite coil embolization. The main disadvantage with *n*-BCA is non target embolization.²⁴ The reported risk of bowel ischemia following glue embolization is 5.4% in upper gastrointestinal tract and 6.1% in lower gastrointestinal tract.²⁵ Stent graft was placed in four patients (two in splenic artery and two in

SMA). Stent graft is safe, effective, and alternate to embolization and has advantage of maintaining distal flow.^{24,26}

Rebleeding rate following endovascular management for pancreatitis-related bleeding varies from 2.6 to 37%.^{9,11,14,15} Rebleeding was seen in seven (6.8%) patients in the present study. Six patients were managed by reintervention. Four patients had rebleeding from the same vessel and two patients had bleeding from a different vessel. Etiology for rebleeding is not known. Ongoing inflammation and enzyme

mediated destruction of the vessel might lead to continued vessel wall injury, rebleeding, or new pseudoaneurysm formation.^{9,11}

Empirical embolization was performed in three patients. The role of empirical embolization in pancreatitis-related hemorrhage is not proven. Hyare et al performed empirical

embolization in eight patients and achieved successful hemostasis in six patients.¹¹ Empirical embolization may be considered in angiography-negative patients with high clinical suspicion of bleeding. Selection of artery for empirical embolization is based on endoscopy findings and angiography findings such as an attenuated vessel and irregular margins of an artery.

Splenic infarct was seen in 18 (17.1%) patients, of which 15 were self-limiting. Splenic abscess and sepsis were seen in three patients. Two patients were managed conservatively and by splenectomy in one patient. Embolization-related complications in the present study are comparable to the reported incidence ranging from 18 to 22%.^{9,21,27} Mortality rate following endovascular management varies from 0 to 20%.^{10-12,14,15,17} Mortality rate in the present study was 1%.

Our study has significant limitations. This is a retrospective study and included only patients who underwent embolization procedure at one institution. We did not include patients who underwent surgical management as the first option for pancreatitis-related bleeding. In addition, the outcomes were limited to 30 days.

Table 3 Details of endovascular interventions and outcomes

Endovascular intervention	No. of patients (%)
Coils	72 (68.5)
<i>n</i> -BCA	21 (20)
Coils and <i>n</i> -BCA	8 (7.6)
Stent graft	4 (3.8)
Outcome	
Technical success	103 (98)
Clinical success	96 (93.2)
Rebleeding	7 (6.8)
Mortality	1 (1)

Abbreviation: *n*-BCA, *n*-butyl cyanoacrylate.

Fig. 3 A 44-year-old male patient with chronic pancreatitis and upper gastrointestinal bleeding. (A) Selective angiography of gastroduodenal artery showing pseudoaneurysm from the pancreaticoduodenal arcade. Coil embolization of superior pancreaticoduodenal artery was performed. Postembolization (B) hepatic and (C) superior mesenteric artery angiography show no pseudoaneurysm.

Fig. 5 A 32-year-old male patient with chronic pancreatitis and pain abdomen. (A and B) Superior mesenteric artery (SMA) angiography showing pseudoaneurysm arising from the SMA. (C) A stent graft was placed to exclude the pseudoaneurysm. (D) Post-treatment angiography showed no pseudoaneurysm.

Fig. 4 A 35-year-old male patient with chronic pancreatitis and a pseudoaneurysm of the pancreaticoduodenal arcade on computed tomography. (A) Selective gastroduodenal artery angiogram showed pseudoaneurysm of the inferior pancreaticoduodenal artery (IPDA). (B) Coil embolization of the IPDA was performed. (C) Superior mesenteric artery (SMA) angiography showed refilling of the pseudoaneurysm. (D) Embolization was performed with *n*-butyl cyanoacrylate. (E) Postembolization SMA angiography showed no refilling of the pseudoaneurysm.

Conclusion

Endovascular management is safe and effective in the management of pancreatitis-related hemorrhage. A high technical and clinical success, low rebleeding rates, low complication, and low mortality rates in this study provide further support for endovascular therapy in pancreatitis-related hemorrhage.
