Abstract

Proton beam therapy (PBT), because of its unique physics of no-exit dose deposition in the tissue, is an exciting prospect. The phenomenon of Bragg peak allows protons to deposit their almost entire energy towards the end of the path of the proton and stops any further dose delivery. Bragg peak equips PBT with superior dosimetric advantage over photons or electrons because PBT doesn't traverse the target/body but is stopped sharply at an energy dependent depth in the target/body. It also has no exit dose. Because of no exit dose and normal tissue sparing, PBT is hailed for its potential to bring superior outcomes. Pediatric malignancies is the most common malignancy where PBT have found utmost application. Nowadays, PBT is also being used in the treatment of other malignancies such as carcinoma prostate, carcinoma breast, head and neck malignancies, and gastrointestinal (GI) malignancies. Despite advantages of PBT, there is not only a high cost of setting up of PBT centers but also a lack of definitive phase-III data. Therefore, we review the role of PBT in current day practice of oncology to bring out the nuances that must guide the practice to choose suitable patients for PBT.

Keywords

- Bragg peak
- pediatric malignancies
- normal tissue sparing
- PBT

Introduction

It is said that no other branch of medicine has benefited more from technological innovations in the last two decades as the branch of oncology. The same is reflected in intensified research in radiation oncology in the last two decades.¹ It is estimated that up to 60 to 70% patients requiring cancer treatments need radiation therapy.² Over a century, technical advancements in radiation oncology, like three-dimensional conformal radiotherapy (3D-CRT), intensity modulated radiotherapy (IMRT), volumetric modulated radiotherapy (VMAT), and image-guided radiotherapy (IGRT) have facilitated the delivery of photon therapy with precision. However, the dose deposited in the surrounding normal tissues albeit less still remains a concern in photon therapy.³ Proton beam therapy (PBT), because of its unique physics of no-exit dose deposition in the tissues,

is an exciting prospect.^{4,5} PBT was first proposed by Wilson⁶ in 1946. Later, the Lawrence–Berkeley National Laboratory published their first PBT patient series.⁷ Thus far, PBT has been used in the clinical setting for over 60 years, and has been applied to 10s of thousands of patients with different types of cancers.⁸

The clinical benefits of PBT include a potential for fewer side effects compared with photon therapy. However, the exact role of PBT remains controversial. This is primarily due to a nonexistence of clear cut benefit for every clinical situation and the high treatment costs associated with the cost of proton facility building and maintenance. More research, studies and discussions are required to address the use of PBT in several types of cancer because of the potential of maintaining a relatively higher quality of life of patients while achieving cure. The aim of this review was to report the characteristics and current developments in PBT.

Biology of Proton Beam Therapy

All through the history of radiation therapy, patients have been treated with photon beams which are gamma rays or X-rays. Both gamma rays and X-rays are physically one and the same thing and differ only in their method of generation, where gamma rays are generated from naturally radioactive elements like Cobalt-60 and the X-rays are produced via man-made linear accelerators. The growth of radiation oncology has been on various ways of administering these photon beams. These photons have been used with basic shielding of critical areas in early years or later by beam shaping with 3D-CRT. Now, these photons are used by modulating their deposition on the target by firing them in a controlled manner from all directions with a sophisticated computerized controlled planning and execution, this is the principle behind IMRT and VMAT. These photons have been used for treatment not just by employing better shielding and modulation but also by altering the dose and fractionation which can give a beneficial biological effect, for example, hypofractionation, hyperfractionation, integrated boost techniques, and stereotactic body radiotherapy (SBRT).

Now with PBT, we have a different beam altogether from the traditional photon beam. It is for this reason that it behaves very differently from photons. While the traditional photons are almost weightless, the proton is almost 800 times heavier than electron. This large mass gives a proton its momentum that gets quickly dissipated after traveling a defined distance in patient's body, this stops the proton from travelling a large distance in the patient's body. This leads to a sharp rise in energy deposition toward the end of the path of the proton and stops any further dose delivery. This phenomenon is referred to as the Bragg peak.⁹ Bragg's peak equips PBT with superior dosimetric advantage over photons or electrons because PBT doesn't traverse the target/body but is stopped sharply at an energy-dependent depth in the target/body. It also has no exit dose (→ Fig. 1). Conversely, when treated with photons the normal tissues do receive low radiation doses and the benefit of PBT can clearly lie in particularly minimizing low dose areas to normal tissues.

Fig. 1 The dose produced by a native and by a modified proton beam in passing through tissue, compared with the absorption of a photon or X-ray beam

The relative biological effectiveness (RBE) of protons can be defined as the ratio of the dose of a reference beam (Cobalt-60 beam) required to produce a specific effect in a biological system to the physical dose of proton radiation required to produce the same effect. Its value is not fixed, but for 70 to 250 MeV, protons range typically from 0.9 to 1.9, with an accepted "generic" value of 1.1 in clinical proton therapy.¹⁰

The traditional PBT is riddled with uncertainties.¹⁰ There are uncertainties in range or depth of Bragg's peak, uncertainties in biological effectiveness due to variable deposition of energy, uncertainties in dose delivery due to variations in interactions with different electron densities of tissues (e.g., electron density of bones is high and is very low for lungs), and then there are uncertainties of doses delivered due to position of mobile organs.¹⁰ However, with the current day pencil beam scanning, these are getting minimized for better treatments with lesser uncertainties.

PBT for different cancers is described below:

1. Prostate cancer: According to Cancer Research UK,¹¹ there is an estimated 17 million new cases of cancer globally. The top four cancers occurring worldwide are lung, breast, bowel, and prostate cancer (CaP), respectively. Due to the long survival and relatively higher doses of radiation therapy, there was an interest in PBT for treatment of CaP for a possible further decrease in doses to normal tissues and better quality of life. Several dosimetric studies have demonstrated that proton therapy for prostate cancer could lower the mean dose to the rectum and bladder compared with VMAT.¹²⁻¹⁴ However, due to the close anatomic relation of bladder and rectum, there is no advantage in terms of the sparing these organs from the high dose volume. In a retrospective study, Takagi et al¹⁵ evaluated long-term outcomes of proton therapy in prostate cancer with a median follow-up of 70 months. Almost 99% of the patients received a dose of 74 Gy. For the low-, intermediate-, high-, and very-high-risk groups, the 5-year failure-free biological recurrence was 99, 91, 86, and 66%, respectively, and the 5-year cancer-specific survival was 100, 100, 99, and 95%, respectively. Grade 2 or higher late gastrointestinal (GI) and genitourinary toxicities were reported to be 3.9 and 2%, respectively.

Study by Kase et al¹⁶ reported results of a dosimetric study comparison between passive-scattering proton beam (PSPT) and intensity-modulated PBT (IMPT) and reported a further decrease in doses to some organs at risk (OARs).

Therefore, while there is dosimetric data of a numerical decrease in doses to surrounding areas, the high-dose areas which are a primary concern in CaP treatment do not get affected. The exact clinical value of further decrease in low-dose areas with PBT needs to be evaluated. One important aspect of studies on PBT in CaP¹⁵⁻¹⁷ is the fact that the target volume in all of them is just the prostate and surrounding tissues with the extent of depending on risk assessment. However, most studies with IMRT and IGRT include not just the prostate and surrounding tissues

as per assessment but also include pelvic nodal stations although the same is debatable and an ongoing trial RTOG (radiation therapy oncology group) 0924 seeks to resolve the same.¹⁸ Also, an ongoing phase-III trial, The Prostate Advanced Radiation Technologies Investigating Quality of Life (PARTIQoL) comparing PBT to IMRT is ongoing to evaluate quality of life, toxicity in low, and intermediate risk CaP.¹⁹ There is also some concern with regards to the interfraction uncertainties introduced by organ filling.

The results for hypofractionated RT (HRT) reported in RTOG 0415 (70 Gy at 2.5 Gy/fractions),²⁰ the CHHiP trial (60 Gy at 3Gy/fraction),²¹ and HYPRO study (64.6 Gy at 3.4 Gy/fraction)²² established the hypofractionated regimen in the treatment of carcinoma prostate. ChhiP trial reported grade 2 or worse bowel and bladder adverse events at 11.9 and 11.7% in the 60 Gy group. RTOG 0415 reported in hypofractionated arm grade-3 GI toxicity at 4.6% and grade-3 genitourinary toxicity at 6.4%. All the reported results were noninferior between conventional and hypofractionated arm.²⁰⁻²²

A study²³ from Japan reported results on 526 patients receiving either conventional fractions for low and high risk CaP (74 Gy/37 fractions and 78 Gy/39 fractions) or hypofractionated proton therapy (HFPT) for low risk CaP (60 Gy/20 fractions and 63 Gy/21 fractions). The authors reported acute genitourinary toxicities greater than grade 2, rates at 5.9% for HFPT. While these results were better for HFPT as compared with conventionally fractionated PBT, the absolute rates are quite comparable as reported in photon based hypofractionated studies.²⁰⁻²² These findings were corroborated in the single arm phase-2 study²⁴ on HFPT for low- and intermediate-risk CaP.

As of date, it may be wise to refer patients with low risk CaP, very large and odd-shaped prostate or ones requiring high doses to critical areas (for e.g., a large avid perirectal lymph node) for PBT because the benefit of numerically lower doses will likely be more when the overall volumes are high or are closely related to critical structures. Hypofractionated approach in itself may not justify PBT in view of similar toxicity outcomes for photons and PBT based studies as discussed above.

2. Pediatric cancers: PBT, as we know, achieves better target coverage with lower volumes of normal tissues receiving lower doses. It can result in up to 50 to 70% reduction in the integral dose as compared with photon beam radiotherapy.²⁵ Although there has been a significant progress in RT technology,²⁶ the concerns about acute and long-term side effects remain. This issue assumes more importance in pediatric age-group due to the ongoing development of organs and tissues and a relatively longer life expectancy in childhood cancer survivors which makes them vulnerable to the effects of radiation on growth, intellectual development, endocrine organ function, and secondary cancer development. Therefore, the pediatric radiation dose to normal tissues should be reduced as much as possible where PBT is valuable.²⁷⁻³¹ For this reason, PBT may be useful for the treatment of pediatric cancers. A retrospective observational study of pediatric patients who received

PBT was reported in 2017. The 5-, 10-, and 20-year rates for grade 2 or higher late toxicities were 18, 35, and 45%, respectively, and those for grade 3 or higher late toxicities were 6, 17, and 17%, respectively. No malignant secondary tumors occurred within the irradiated field.³² Colaco et al showed that the tumor control rate and survival outcomes in proton therapy for treating pediatric patients diagnosed with central nervous system cancer were comparable to that of photon therapy with significant reduction in acute and late toxicities. There was also decrease in the severity of endocrine, neurological, intelligence quotient, and quality of life deficits including lesser ototoxicity.^{33,34}

While there is no doubt that the dosimetric advantage of PBT may be best suited for pediatric age group, it is worth mentioning that critical clinical data on the long-term effectiveness, and harms associated with the use of PBT in most pediatric cancers is not available. There is still need for high quality research in this matter.

As of date, it may be wise to refer the pediatric age group for PBT except for the tumors needing small doses like Wilms' tumor.

3. Breast cancers: While adjuvant radiation therapy for breast cancer (CaB) is important for local control and survival benefit,³⁵ it is a known fact that long-term cardiovascular toxicities and second cancers induced by RT may counteract the survival benefit.^{36,37} PBT can reduce the mean dose to heart to approximately 0 to 0.5 Gy for left-sided breast cancer.³⁸ A systematic review published in 2019 recommends the mean heart dose to be less than 2.5 Gy.³⁹ A recent systematic review reported doses using modern radiotherapy practices (photon based).⁴⁰ They reported that the mean heart dose for left-sided breast cancer, reported by 84 studies (studies published between January 2014 and September 2017) was 3.6 Gy, compared with a review of those previously reported (5.4 Gy). They further reported that the regimens employing breathing control in any position had a significantly lower mean heart dose (1.7 Gy) compared with regimens without breathing control (4.5 Gy; $p < 0.0001$).

Therefore, it can be appreciated that the modern day regimens are already keeping the dose to heart at an acceptable level. Furthermore, it was reported in a recent paper that the estimated absolute risk of cardiac mortality from modern radiotherapy were approximately 1% for smokers and 0.3% for nonsmokers.⁴¹

In the recent years, relative success of accelerated partial breast irradiation (APBI) and PBI has also reduced the target volumes in breast for the radiation oncologist. This decreases the scatter dose to the heart even further.^{42,43}

Keeping all the above in perspective, we can realize that the lower dose to heart possible with PBT may not be clinically useful for most cases.

To further determine and evaluate its cardiovascular effects, an ongoing prospective phase-II trial (NCT01758445) on patients receiving PBT for stage-II/III breast cancers has been undertaken.

However, it will be wise to consider PBT for special situations. For example, an early-stage tumor on left side

especially in the inner/central quadrant⁴⁴ or a locally advanced breast cancer on left side requiring internal mammary node radiation.³⁸ In above-mentioned or any other situations, physical properties of PBT may help some patients, especially where modern radiotherapy techniques may not be yielding enough dosimetric benefits.

4. **Hepatocellular carcinoma:** Hepatocellular carcinoma (HCC) is a primary liver cancer believed to originate from primary stem cells. The treatment of choice is surgery but most patients are seen in an inoperable stage⁴⁵ and then the intent of treatment becomes palliative by prolonging the liver function for as long as is possible. The problem with delivering RT to this tumor is the inherent radio-sensitivity of the surrounding normal liver parenchyma. This problem is partly solved by SBRT using photon beam. Méndez Romero et al⁴⁶ reported local control rates at 1 and 2 years for the whole group (which included liver metastases) were 94 and 82%. A Korean group reported that higher RT doses (cumulative and per fraction) are required to achieve the same tumor control probability for larger lesions.⁴⁷ This is where benefit of PBT can be explored. A dosimetric study has shown that IMPT (intensity modulated PBT) could decrease the dose delivered to organs at risk compared with IMRT-based SBRT.⁴⁴ This allows us the possibility to increase the dose given to the tumor without increasing radiation-induced liver damage.^{48,49} Sugahara et al reported their results of a retrospective study⁵⁰ on 22 patients with large HCC (median size: 11 cm, range: 10–14 cm). The patients were treated with proton therapy to a dose of 72.6 cGyE and they demonstrated promising result with a 2-year local control (LC) of 87%, 2-year overall survival (OS) of 36%, 2-year progression-free survival (PFS) 24% with no grades 3 to 5 late toxicities. PBT has the potential to reduce radiation-related hepatotoxicity and allow for tumor dose escalation; however, due to the retrospective nature of the data, true survival benefit cannot be commented upon unless phase-3 trials are undertaken. The reason for the latter is the fact that even the benefits of liver transplant are not seen beyond certain size criteria.⁵¹ The same is likely attributable to the fact that larger sized tumors are more aggressive.⁵² NRG-GI003 (NCT03186898) is a recently opened phase-III randomized trial that will determine if PBT will confer an OS advantage compared with photons in unresectable HCC patients.

Lastly, a recent publication from Japan examined 83 recurrent HCC cases after initial PBT. There were multiple dose-fractionation combinations for both primary and reradiation therapy (reRT; determined by tumor location within the liver), with 60 GyE in 10 fractions and 72.6 GyE in 22 fractions being the most common. Two-year survival was 88%, and no patient experienced grade 3 or higher adverse events.⁵³

Currently, those patients with an upfront large tumor size that requires SBRT may be referred for IMPT based proton therapy if a sufficient dose to target is not achievable without significant damage to liver parenchyma. Also, a recurrent HCC amenable to SBRT will benefit with superior dosimetry of PBT.

5. **Head and neck tumors:** The most common of these are squamous cell carcinomas of head and neck (HNSCC). RT is an important treatment modality for HNSCC. PBT has shown an advantage to minimize doses to the brain stem, salivary glands, spinal cord, pharynx, and larynx in comparison with RT including newer techniques of IMRT and VMAT.⁵⁴⁻⁵⁷ A case-matched dosimetric analysis of 25 patients reported significant reduction to doses to OARs when IMRT was compared with IMPT.⁵⁸ Ramaekers et al⁵⁹ explored the cost-effectiveness of IMPT with IMRT in HNSCC using NTCP models and comparative planning studies. At 12 months, the predicted occurrence of xerostomia and dysphagia was found to be lower with IMPT (22 and 18%) than with IMRT (44 and 23%). However, PBT does not improve survival outcomes as compared with IMRT.⁶⁰ One site which may particularly benefit with PBT is nasopharyngeal (NPC) and sinonasal carcinoma because of its special anatomic location with its close proximity to eyes, neural structures, and cranial nerves. The advantage on dosimetry for proton therapy over IMRT is a significant reduction of normal tissue volumes receiving lower radiation doses.^{61,62} A recent report by Lewis et al⁶³ reported their findings on nine NPC patients who were treated with PBT and concurrent cisplatin-based chemotherapy. They reported a 2-year LC and OS was 100 and 88.9%, respectively. No patients had acute grade-4 or -5 toxicities. They reported only grade-2 mucositis in eight patients and grade 3 in one patient. These outcomes are quite encouraging due to low-adverse events with LC and OS results that are similar to prior reports of IMRT.⁶⁴

While the dosimetric advantage can be appreciated in the available dosimetric studies, there is no prospective phase-3 study toward use of PBT in head and neck cancers. A prospective randomized study between PBT and IMRT comparing the toxicity as a primary outcome is currently recruiting (NCT01893307). Therefore, to judge the need for PBT for any particular case, a model-based approach is recommended where existing NTCP models are used to choose those patients who stand to benefit in terms of avoiding toxicity, and thereby decreasing their morbidity and costs.^{64,65}

PBT, due to its potential advantages, may result in clinically meaningful reductions in toxicities and complications in reRT for HNSCC. Many series including two prospective studies have been published in this regard to date. The results are dependent on patient selection, rates of salvage surgery, use of concomitant chemotherapy, and histology of the tumor. ReRT is not devoid of toxicity, most series report similar acute toxicity and mortality. One of the initial report regarding PBT ($n = 34$) with recurrent cavity cancer utilized concurrent intra-arterial chemotherapy.⁶⁶ With a retreatment median dose of 50 GyE-2-year LC was 62% and 2-year OS was 42%. Although no patient experienced grade 4 and 5 toxicities, several suffered grade-3 mucositis (32%), dermatitis (29%), and dysphagia (35%). One multi-institutional retrospective study⁶⁷ ($n = 92$) evaluating reirradiated passive scatter proton therapy (PSPT) reported 1-year locoregional

control of 75%, and OS rate of 65.2%. Authors reported that acute grade-3 adverse events from PBT reRT were lower than historical IMRT reRT series. A median of 34 months elapsed between treatments. Another series from MD Anderson Cancer Center ($n = 60$) reported the rates of locoregional failure free and OS at 1 year 68.4 and 83.8%, respectively.⁶⁸ The median interval from initial to retreatment was 47 months. The rate of feeding tube placement was 10% and grade-3 dysphagia and xerostomia was seen in three and two patients respectively. The authors correlated clinical target volume $>50 \text{ cm}^3$ with greater risk of grade >3 toxicities. McDonald et al⁶⁹ evaluated 61 patients with full-dose initial (median: 65–66 Gy). At a median 15-month follow-up, the LRR was 20%, but the 2-year OS markedly differed from the previous study (33% in this series). Grade-3 mucocutaneous toxicities were seen in eight patients and 1 person died of RT-induced brainstem edema leading to a fall and hematoma. On multivariate analysis, factors portending risk of local failure included presence of gross (versus microscopic) disease, and size of the gross tumor volume. ReRT dose, when analyzed as a continuous variable, independently correlated with local control. ReRT in HNSCC has always been dismal clinical scenario with varied outcomes and toxicity and PBT results do look exciting. A recent publication by multi-institution reirradiation (MIRI) collaborative group⁷⁰ reported results on 412 recurrent or second primary HNSCC patients reirradiated with IMRT. They reported encouraging results with 2-year survival of up to 62% in recursive partitioning analysis (RPA) class-I patients. The overall rates of acute grade-3 toxicity were 19% and cumulative incidence of late toxicities was 14.2%. This study although retrospective, reports results of a large cohort of patients and results may be considered equivalent to PBT results discussed above.

SBRT with photons is an emerging modality for treatment of recurrent HNSCC. A recent publication⁷¹ reported a 2-year survival for patients with tumor size less than 25 cc where more than 35 Gy dose could be safely given. The acute grade-4 toxicity reported in group receiving SBRT was less than 1%.

Therefore, it can be appreciated that survival outcomes for recurrent HNSCC patients depends upon time to recurrence, operability, and size or volume and presence of organ dysfunction. Toxicity reports for non-PBT therapies of IMRT and SBRT are not dismal and are may be even equivalent.

However, the heterogeneity within recurrent HNSCC cases forbids us to generalize and recommend any one particular modality (IMRT, SBRT, or PBT) for RT. The decision may be empirically based on closeness to critical structures. Ideally MIRI RPA class I must receive fractionated RT (preferably with chemotherapy)⁷⁰ and if such a planning target volume (PTV) is reasonably close to critical structures (especially neural), then the same may not be possible with IMRT and PBT may be preferable. Regarding MIRI RPA class II where PTV that may be too close to the critical structures, and it is not possible to consider the patient for fractionated RT, then we can go for SBRT if the volume

is less than 35 cc or for fractionated PBT with concurrent chemotherapy.

ReRT with PBT in this scenario has a high potential for minimizing toxicities and as systematic randomized study with suitable RPA class groups with QOL analysis is much needed.

6. Skull base chordoma: Chordoma is a rare, locally aggressive, slow-growing primary bone tumor. It occurs typically on either end of the notochord, which during development transforms into the sacrum and the skull base. Traditionally, they have been addressed with surgery, but the extent of surgical resection at the skull base is often limited by the surrounding critical neurovascular structures. Subtotal resections are, therefore, common and residual tumors are meant to be treated by radiation therapy.⁷² Chordoma cells are considered relatively radioresistant when treated with conventional fractionated external beam protocols, and therefore, high doses are warranted.⁷³ Due to its proximity to neural tissue and the higher dose requirement, PBT is evolving as the postoperative treatment of choice.^{74,75} A review reported results of 416 cases of advanced or incompletely resected tumors comparing photons to PBT, PBT showed better results with the best long-term (10 years) outcomes with relatively few significant complications considering the high doses delivered with this therapeutic modality.⁷⁶ Another review conducted in 2018 concluded that despite advances in proton therapy, recurrence rates in skull base chordoma remain high.⁷⁷ Large case series demonstrated that unfavorable tumor control was often linked to high residual volumes ($>23 \text{ cm}^3$) and brainstem involvement.^{78–80} Authors recommended that due to the radioresistant behavior of this neoplasm, a delivery of a dose of at least 74 Gy (RBE) to the tumor bed and other sites of gross disease is recommended. As an alternative to PBT, modern technology in conformal photon irradiation can offer encouraging control rates. In a recent report on 24 patients treated with IMRT and IGRT to a median dose of 76 Gy, the overall 5-year loco-regional control (LRC) was 65.3%.⁸¹ Larger tumor volume of tumor ($>60 \text{ cc}$) and reirradiation were significant prognostic factors predict inferior survival.⁸²

Due to the close proximity to brain stem, it is very challenging to treat these patients with an ideal dose of 76 cobal grey equivalent (CGE) even with modern technology for photon beam RT therefore PBT seems to be a very exciting clinical tool. However, due to the very same reason of close proximity with the dose and range uncertainties of PBT, it may not always be possible to control dose to brain stem so easily. This is due to the fact that the dose needed to treat chordomas and chondrosarcomas is a high dose of greater than 70 CGE and the dose tolerable to brain stem is just a maximum voxel dose of 60Gy. This steep fall-off may not always be possible due to their close proximity. However, PBT may still be our best hope for better dosimetry in this critical location. Also, prospective trials are currently being conducted to compare the biological effectiveness and safety of carbon-ion therapy with PT for skull base chordomas.⁷⁴

7. GI tumors: PBT has been explored in gastrointestinal tract tumors with the aim to reduce toxicities. In a study from Florida, 22 patients were treated with proton therapy and concomitant capecitabine (1,000 mg per orally twice daily) for resected ($n = 5$); marginally resectable ($n = 5$) and unresectable/inoperable ($n = 12$) biopsy-proven pancreatic and ampullary adenocarcinoma.⁸³ Proton doses ranged from 50.40 to 59.40 CGE. Median follow-up was 11 months. No patient demonstrated any grade-3 toxicity during treatment or during the follow-up period and grade-2 GI toxicity was eliminated ($p = 0.0009$) in patients treated with plans that avoided anterior and left lateral fields which were associated with reduced small bowel and gastric exposure. Mizumoto et al reported 51 patients with esophageal cancer who were treated between 1985 and 2005 using proton beams with or without photons.⁸⁴ There was no treatment interruption and the overall 5-year actuarial survival rate was 21.1% and the median survival time was 20.5 months. The 5-year local control rate for all 51 patients was 38.0% and the median local control time was 25.5 months. Studies have evaluated role PBT in recurrent GI neoplasms. Ono et al reported the results of multicenter retrospective study in Japan with 202 (including 90 inoperable) esophageal cancer patients.⁸⁵ The 3-year and 5-year OS was 66.7 and 56.3%, respectively. The 5-year LRC was 64.4%. This study suggests that PBT for esophageal cancer was not inferior in efficacy and had lower rates of toxicities in comparison to photon radiotherapy.

These studies report encouraging results with PBT for GI cancers. Though lower grade-2 toxicities are inspiring, a randomized study with an assessment of quality of life shall be very helpful in recommending PBT for these patients.

8. Lung cancers: PBT is associated with more uncertainty due to finite range of proton beam and motion for thoracic cancers. It is less forgiving in moving lung cancer due to the Bragg peak's sensitivity to motion, anatomy, and density changes. Although PBT is improving rapidly as more research is performed with the implementation of four-dimensional computed tomography (CT)-based motion management and IMPT.⁸⁶ In the middle of 1990s, the Loma Linda University lung cancer program developed techniques for managing early-stage NSCLC using PBT, they intensified the dose to 70 Gy (RBE) over 10 fractions.⁸⁷ This led numerous proton centers in Japan and United States to consider hypofractionated and accelerated PBT to manage stage-I NSCLC.⁸⁸⁻⁹⁰

A study compared PSPT, IMPT, and photon-based radiotherapy to deliver SABR, 50 Gy in four fractions in centrally located stage-I NSCLC, and reported significant reduction of radiation doses to critical structures.⁹¹ Other studies reported that the proton-based SBRT plans delivered a lower radiation dose to lungs, esophagus, bronchial tree, and spinal cord.^{92,93} PBT was noted to deliver a slightly higher radiation dose to the skin and chest wall when less than three beams were used but was overcome by use of a greater number of proton beam fields or arc therapy. As expected, PSPT is not better for dose reduction

for esophagus, lung receiving 20 Gy, or higher. However, optimized PSPT better controls lung V5 and spares better than contralateral lung, spinal cord, heart, and integral dose compared with photon plans.^{94,95}

A major limitation to proton therapy in early NSCLC was the lack of volumetric image guidance, thereby requiring slightly larger PTV margins for uncertainty.

While the doses to OARs is lower with PBT (especially with IMPT) the clinical outcomes remain similar and therefore PBT may be better suited for patients where lowering the volumes of normal tissues that receive the low doses shall be clinically meaningful. For example, patients with larger early stage tumors, smaller overall lung volume, tumors located more centrally, or those that are close to the brachial plexus. Also, like always PBT may be considered for patients who don't meet dosimetric constraints with photon based SBRT.

A phase-II study of 44 patients with stage-III NSCLC who received 74 CGE via conventional fractionation (two CGE per fraction) with weekly concurrent carboplatin and paclitaxel, reported no grade-4 or -5 toxicities, and minimal grade-3 toxicities.⁹⁶ The median survival was 29.4 months, as compared with 20.3 months of 74 Gy arm in RTOG 0617. Two similarly designed studies that included fewer patients, demonstrated equally excellent outcomes.^{97,98} An ongoing phase-III study RTOG 1308 comparing IMRT to proton therapy in stage-III NSCLC seeks to evaluate OS as its primary objective. A randomized study to compare IMRT with IMPT using an integrated boost approach to boost GTV to 72 Gy, while keeping PTV dose to 60 Gy with concurrent chemotherapy is ongoing. Two studies are currently exploring hypofractionation with concurrent chemotherapy including a single institutional study and a multicenter study being done through the Proton Collaborative Group (PCG).

Due to these controversies of range uncertainty and motion management, there is much debate in the oncology community about which lung cancer patients benefit significantly from proton therapy. PBT could be the answer to successful dose escalation especially in large treatment volumes encountered in stage three NSCLC. Often such patients are taken up for neoadjuvant chemotherapy to no particular survival benefit with a higher toxicity.⁹⁹ PBT should be particularly beneficial to patients who have poor pulmonary function, cardiovascular disease, recurrent disease, or other individuals at high-risk to develop severe side effects in general (such as the elderly).

9. Reirradiation with PBT: Locoregional recurrences within the previously irradiated fields are common even with the advancement in radiation techniques, newer systemic therapies, and improved surgical techniques. Reirradiation is challenging in effective and safe dose delivery and the dosimetric advantage of proton therapy makes it an exciting option to reirradiate with minimal toxicity to normal tissues.

In a study by Dionisi et al,¹⁰⁰ 17 recurrent NPC were treated by PBT with median reirradiation dose of 60 Gy RBE (range: 30.6–66) with median follow-up of 10 months. 53% of patient underwent concomitant chemotherapy.

No adverse grade-3 acute toxicity seen and late grade-3 toxicity seen in 23.5%, with hearing impairment in 17.6%. Two patients developed grade-2 soft tissue necrosis and grade-5 carotid blowout occurred in one patient. Overall survival was 54.4% and local control was 66.6%.

Retrospective study on PBT with IMPT reirradiation of thoracic malignancies with definitive intent was done by Ho et al. The study included 27 patients. 93% of patients received IMPT for thoracic cancer recurrence and 7% patients received sequential PBT after a course of SABR. A median dose of 66 Eq. D2 Gy (range, 43.2–84 Gy). The median time to reirradiation was 29.5 months and median follow-up for all patients was 11.2 months (25.9 surviving patients). The 1-year LRFS and PFS were 84 and 76%, respectively. Late grade-3 pulmonary toxicity developed in two patients and grade 4–5 toxicities was not seen in any patient.¹⁰¹

Fifty patients (2011–2016) who received PBT reirradiation for breast cancer got registered in the PCG.¹⁰² Median follow-up of 12.7 months (range: 0–41.8) and 60 Gy (range: 10–96.7) of median prior RT dose were given. Median reirradiation dose was 55.1 Gy (range: 45.1–63 Gy) and 110.6 Gy (range: 70.6–156.8) of median cumulative dose. Median interval between RT courses was 103.8 months (range: 5.5–430.8). A total of 84% regional nodes was included in reRT in which 66% were internal mammary node (IMN). At 1 year, LRFS was 93%, and OS was 97%. Grade-3 events occurred in patient with body mass index (BMI) more than 30, IMN reirradiation and bilateral breast cancer with acceptable toxicity in spite of median cumulative dose exceeding 110 Gy.

Fifteen patients with isolated, locally recurrent pancreatic cancer were treated with PBT were analyzed from 2010 to 2015. Median follow-up was 15.7 months (range: 2–48 months). Concurrent chemotherapy was received by 67% of the patients and median PRT dose was 59.4 Gy (range: 37.5–59.4 Gy) with median time interval of 26.7 months (range: 7–461.3 months). Acute $\geq$ grade-3 toxicities was seen in 13% of patients. One-year OS was 67% and “in-field” failure-free survival at 1 year was 87%. LPFS and DMFS at 1 year was 72 and 64%, respectively, with a higher median survival found with concurrent chemotherapy.¹⁰³

Fifteen patients of recurrent rectal and anal cancer were analyzed using a hyperfractionated or accelerated reRT by PBT from 2007 to 2017 with a median prior pelvic RT dose of 50.4 Gy (range: 25–80 Gy) and median time interval of 4.7 years (range: 1.0–36.1 years). Total reRT dose was 39 to 45 Gy (RBE) along with concurrent chemotherapy to all patients. As compared with photon therapy PBT achieved lower mean pelvic bone marrow dose and acute or late grade-4 toxicity was not seen in any patients.¹⁰⁴

In a prospective study, 14 patients were enrolled for thoracic reirradiation between 2010 and 2014. All 14 patients had history of thoracic radiation and newly diagnosed or locally recurrent esophageal carcinoma. All patients received proton beam reirradiation. The median

reirradiation dose was 54.0 Gy (RBE; range: 50.4–61.2 Gy) and median cumulative dose was 109.8 Gy (range: 76–129.4 Gy). Concurrent chemotherapy was received by eleven patients. The median interval between radiation courses was 32 months (range: 10–307 months) and the median follow-up was 10 months (range: 2–25 months). This study¹⁰⁵ showed comparable acute and late toxicity with good local control with maximum radiation related grade-2 toxicity of 64%.

The potential advantage of PBT in reirradiation of meningioma is due to lower integral brain dose. Sixteen patients were retrospectively analyzed who received prior median dose of 54 Gy (range: 13–65.5 Gy). Median time from prior RT to PBT, reRT was 5.8 years (range: 0.7–18.7 years) and median PBRT dose was 60 Gy (RBE; range: 30–66.6 Gy). Median follow-up was 18.8 months. Patients with initially grade-I tumors and longer interval between prior RT and PBRT had improved PFS. Late grade-3 toxicity was 31% and 13% developed radionecrosis with good intracranial control.¹⁰⁶

The results with reirradiation for HNSCC were discussed in the relevant section. The other studies reviewed above report reasonably good outcomes with toxicities that are not unacceptably high. The reRT is generally the last option as it is generally advised only when the no other options are beneficial or feasible for a patient. In such a scenario, PBT results are indeed encouraging though high quality phase-3 data with a focus on QOL shall help oncologists make data-driven choices for their patients.

Conclusion and Future Directions

The physical properties of protons provide PBT with unique dosimetric advantages with only few disadvantages. PBT therefore remains a promising treatment which has already shown many positive results. However, the most important benefit that comes is in reduction of low dose volumes which means that the volumes of normal tissues receiving less than 50% of prescribed dose are lesser for PBT but not necessarily the high-dose volumes.⁵⁵ Therefore, we cannot always presume superior outcomes with PBT even though it may be intuitive to do so. It is for this reason that we should encourage phase-3 trials to compare the modalities so that robust data can be obtained for a more scientifically sound decision making for our patients. It is also important to examine long-term clinical outcomes with PBT to truly understand the benefits of PBT.

However, radiation oncology is a branch where tools and techniques always makes a difference and therefore there must be a careful consideration for PBT treatment for pediatric cases and for complex cases in adults where dosimetry may be unsuitable to the planned treatment in terms of coverage and sparing of normal tissues.
