Objective To estimate the serum zinc levels in children under the age of 5 years with febrile seizures and febrile children without seizures

Materials and Methods In this cross-sectional study from 2017 to 2018, 40 children with febrile seizures (simple and complex) were taken as cases. Forty age- and sex-matched febrile children without convulsions were recruited as controls. Serum zinc estimates were analyzed using a spectrophotometer (Biolis 50i–Autoanalyzer).

Statistical Analysis The demographic variables and serum zinc estimates were analyzed using the Mann–Whitney test. The odds ratio was used to calculate the association of zinc deficiency in febrile seizures; 5% level of significance was considered.

Results The mean serum concentrations of zinc in the cases and controls were $83.8 \pm 33.1 \mu\text{g/dL}$ and $116.3 \pm 30.3 \mu\text{g/dL}$, respectively ($p = 0.002$). Hypozincemia defined by “a serum zinc level of less than $63 \mu\text{g/dL}$ ” was found in 12 (30%) cases and 2(5%) controls with an odds ratio of 8:1.

Conclusion Children with febrile seizures had significantly reduced concentrations of zinc in the serum.

Introduction

Febrile seizures are a commonly encountered neurological source of hospital attendance in children with a worldwide incidence of 2 to 8%.¹ The peak age for the occurrence is 18 to 24 months, and the majority (90%) of the children report the first episode before the age of 3 years.² The operational definition proposed by “International League Against Epilepsy,” “a seizure occurring in childhood after one month of age, associated with a febrile illness not caused by an infection of the central nervous system, without previous neonatal seizures or a previous unprovoked seizure, and not meeting criteria for other acute symptomatic seizures” emphasizes the judicious use of select laboratory testing to rule out intracranial infection before making a diagnosis of febrile seizures.³ The age-specific predilection of febrile seizures is still unclear, and a complex interplay of genetic and environmental factors have been postulated. A robust relationship

with febrile seizures and genetic epilepsy (voltage-gated sodium channelopathy) has been established in one-third of children with positive family history.⁴ However, a significant pedigree chart is absent in several children with febrile seizures and routine genetic testing is not warranted. Additional factors considered in the pathogenesis include dyselec-trolytemia (hyponatremia), pyridoxine deficiency, human herpes virus 6, and disorders of trace elements, primarily zinc, iron, and copper.⁵ Among them, zinc status in children with febrile seizures has drawn substantial attention, given its high-concentration in the brain and potential role in synaptic neurotransmission. This has been complimented by animal studies, especially mouse models. Zinc regulates the rate-limiting enzyme in GABA synthesis and also prevents excitatory neuronal discharge by facilitating the inhibitory effect of NMDA receptors.⁶ This largely inhibitory outcome is diminished following hypozincemia secondary to

endogenous pyrogens released during the febrile illness. Data from prospective studies on zinc status in febrile seizures do not run in parallel with conflicting results. Given the limited information from the Indian subcontinent, this study was designed to ascertain the relationship between hypozincemia and febrile seizures in children.

Materials and Methods

This prospective cross-sectional study was held at a tertiary teaching institute in Puducherry, India, over 18 months from January 2017 to June 2018 after obtaining approval from the Institutional Ethics Committee (Ref. No IEC:RC/15/34). Children aged 6 months to five years, who presented to the pediatric outpatient department, satisfying the study definition of febrile seizures were taken as cases, such as children on zinc therapy for diarrhea, pneumonia, acrodermatitis enteropathica, and severely malnourished children; children with dyselectrolytemia; children with clinical signs of intracranial infection were excluded from the study. An equal number of age- and sex-matched febrile children without seizures were taken as controls. Demographic details including birth history, family history, and details about the febrile seizures (age of onset, type of seizure, duration, treatment, and prophylactic therapy) were collected. Parental consent was obtained prior to enrolment. Furthermore, infants underwent cerebrospinal fluid (CSF) analysis to rule out intracranial infections.

Four milliliters of blood samples were drawn within 24 hours of admission. Two milliliters of the samples were centrifuged, and the separated serum was analyzed for zinc levels using a spectrophotometer (Biolis50i- Autoanalyzer) and 560 nm wavelength with the help of a FAR diagnostic kit (zinc reagent = 5bromo, 2pyridylazo-5N-propylN-sulphonopropyl phenol). A serum zinc level of less than 65 mcg/mL was taken as hypozincemia. Also, serum levels of electrolytes (sodium, potassium, calcium and magnesium), C-reactive protein, and albumin levels were analyzed to estimate the bound form of zinc. All children were followed-up until the time of discharge from the hospital.

Data Presentation and Statistical Analysis

The incidence of febrile seizure as per literature was found to be 2 to 5%. With an error of 5% and a confidence interval of 95%, a sample size of 80 children was estimated. The results were recorded on a proforma that was then analyzed using SPSS 20.2 software. The demographic variables were analyzed, and statistical significance was estimated using the Mann-Whitney test. The odds ratio was used to calculate the association of zinc deficiency in febrile seizures. The box and whisker plot was used to analyze statistical significance of serum zinc levels; 5% level of significance was considered.

Results

From January 2017 to June 2018, among the 12330 children presenting to the pediatric outpatient/accident and emergency services, 6480 children with fever were screened for eligibility; 40 children with febrile seizures as cases and 40 febrile children without convulsions as controls were recruited for the study. ► **Table 1** depicts the profile of children recruited in the study. The mean age (standard deviation [SD]) of the cases was 17 months and children aged 12 to 36 months accounted for 55% of all included cases. A slight female preponderance was noted in both groups. Amongst the cases, 30 children (77%) presented with simple febrile seizures and 10 had complex febrile seizures. One-fifth of the cases had a family history of febrile seizures. Twenty-eight cases (70%) sought medical attention for the first episode of febrile seizures, and clonic seizures was the common semiology in 63% of the cases. Pneumonia (40%), viral upper respiratory tract infection (25%), scrub typhus (12%), and urinary tract infection (11%) were the etiology of fever in the control group.

The mean serum concentrations of zinc in the cases and controls were 83.8 ± 33.1 µg/dL and 116.3 ± 30.3 µg/dL, respectively. The mean serum zinc status in the febrile seizure group were significantly different ($p = 0.002$) from the controls (► **Fig. 1**). Hypozincemia, defined by “a serum zinc concentration of less than 63 µg/dL” was found in 12 (30%) cases

Table 1 Clinical characteristics of children with febrile seizures and febrile children without seizures

Variable	Cases (n = 40) (%)	Controls (n = 40) (%)
Females	22 (55%)	19 (47.5%)
Age, in months		
<12	7 (17.5%)	12 (40%)
13–36	22 (55%)	23 (57.5%)
37–60	11 (27.5%)	5 (12.5%)
Fever duration, in hours		
<24	30 (75%)	3 (7.5%)
>24	10 (25%)	37 (92.5%)
Mean peak temperature (°C)	38.4 ± 0.9	38.1 ± 0.6
Etiology		
Viral Upper respiratory tract infection	29 (72%)	10 (25%)
Pneumonia	5 (12%)	16 (40%)
Others	6 (16%)	14 (35%)
Mean serum CRP ($\pm$ SD mg/L)	13.1 ± 4.4	11.8 ± 3.7
Mean serum albumin ($\pm$ SD g/dL)	4.6 ± 1.2	4.3 ± 1.9
Mean serum zinc ($\pm$ SD mcg/dL) ^a	83.8 ± 33.1	116.3 ± 30.3

Note: Data presented as n (%) unless otherwise stated.

^aComparison was statistically significant with p-value of 0.002. Other variables were not statistically significant.

and 2(5%) controls with an odds ratio of 8.1. Furthermore, age, sex, and degree of fever had no significant association with serum zinc levels

Discussion

The current study showed a significantly lower serum concentration of zinc in children with febrile seizures when compared with age- and sex-matched controls of febrile children with no seizures. The results of the study are congruent with the largest study from Nigeria by Okposio et al who assessed zinc status in 180 children.⁷ The mean serum zinc estimates of the febrile seizure group (83.8 µg/dL) was higher than the study from Nigeria. The variation in the serum zinc levels may be attributed to the epidemiological difference in basal zinc and nutritional status of the cohort. A humble attempt at a systematic review by Nasehi et al yielded a temporal association of relatively low zinc levels in children with febrile seizures in comparison to fever-matched controls with no seizures.⁸ However, there are conflicting reports from Celik et al and Cho et al who did not find the difference remarkable.⁹ Weak sample size and technical differences in serum zinc estimation were the reasons ascribed for the poor association. Nonetheless, a critical analysis of the published data provides very little information on the proportion of hypozincemia for risk stratification. In the present study, hypozincemia was noted in 30% of the children with febrile seizures. This is proportionately low when compared with a recent study of 50 children with febrile seizures by Hameed et al in Egypt where hypozincemia was obtained in one half of the cohort.¹⁰ The true incidence of hypozincemia in children with febrile seizures is arguable, as a parallel study from Iran did not identify a solitary case of hypozincemia.¹¹ Rigid criteria of less than 40 for zinc deficiency may be the reason for this dissimilarity in the study.

In addition, lower serum concentrations of zinc are not sine qua non with febrile seizures and has also been evaluated in patients with well-controlled and difficult to control epilepsy. A preliminary study by Wojciak et al resonated with the observation of lower serum zinc levels in children with epilepsy as well.¹² Although it is unclear what the ultimate meaning of these findings portend, it extends the scope for further research into the role of zinc in synaptic neurotransmission and its pathogenesis in seizures. The possible explanation for the low serum zinc status in febrile seizures includes redistribution of zinc into the liver and infection-induced hypozincemia. Zinc is ubiquitous within cells and has pre-defined catalytic, structural, and regulatory functions. During active inflammation secondary to stressors such as fever or seizures, cytokines, which are released as an acute phase response, activate the hepatic synthesis of metallothionein. Metallothionein is an intracellular metal-binding protein which increases the hepatic absorption of zinc with a consequent drop in serum zinc levels.¹³ Elevated C-Reactive protein as a marker for acute phase response has been considered in the interpretation of serum zinc concentrates by Lee et al.¹⁴ Serum zinc and serum CRP estimates in preschoolers with febrile and afebrile convulsions were analyzed and CRP-adjusted serum zinc concentration was remarkably reduced in the febrile seizures group. Retrospective analysis of the samples was one of the drawbacks of the study. The current study did not show any difference in serum zinc levels with age, gender, peak temperature, serum CRP, and serum albumin. This aligns with the similar observations by Mollah et al.¹⁵ A negative correlation between mean serum zinc level and the temperature was observed by Okposio et al. The reason for this inverse relationship is still speculative and the observation has not been replicated in the current study.

The exact pathogenesis of reduced zinc levels and febrile seizures susceptibility remains conjectural. Experimental synaptic zinc transporter knocked out mouse model, demonstrating an increased vulnerability to heat-induced seizures.⁶ This enhanced susceptibility to febrile seizures is hypothesized to lower synaptic concentrations of zinc and its poor constraint of excitatory output modulated by NMDA receptors. This unconstrained NMDA excitability secondary to diminished synaptic zinc concentrates is one of the proposed mechanisms. The enzyme modulatory function of zinc on pyridoxal kinase and resultant GABA synthesis have also been suggested. The full complexity of the role of zinc in epileptogenesis is still unestablished and merits attention.

In conclusion, the present study attends to the existing literature on relatively lower serum zinc concentrations in children with febrile seizures. Hypozincemia in one-third of the study population deserves special mention. The possible role of hypozincemia in febrile seizures, when compared with fever-matched controls without convulsions, needs to be addressed. A combination of zinc concentrates in plasma and CSF with zinc transporter gene polymorphisms may not only shed light on the proposed etiopathogenesis but also offer treatment opportunities.
