Abstract

Objective Japanese encephalitis (JE) is an arthropod-borne flavivirus infection having high mortality and morbidity. This study was performed to evaluate the conventional magnetic resonance imaging (MRI) findings in JE and to find out any difference between pediatric and adult JE.

Materials and Methods This retrospective study was performed on serologically positive 54 JE patients presented to a tertiary care hospital with acute encephalitic symptoms between April 2016 and October 2019. Relevant neurological examination, cerebrospinal fluid analysis, and MRI scan of the brain were performed.

Results Fifty-four JE patients ($n = 31$ males and $n = 23$ females) having 32 pediatric and 22 adult JE were included in the study sample. Group 1 JE ($n = 16$) patients had encephalitic symptoms with duration less than 15 days up to the day of MRI scan and group 2 JE ($n = 38$) had symptoms more than 15 days. Group 1 JE had mean apparent diffusion coefficient (ADC) value of 0.563 ± 0.109 (standard deviation [SD]) $\times 10^{-3} \text{ mm}^2/\text{sec}$ and group 2 JE had 1.095 ± 0.206 (SD) $\times 10^{-3} \text{ mm}^2/\text{sec}$. The mean ADC value of pediatric JE was 0.907 ± 0.336 (SD) $\times 10^{-3} \text{ mm}^2/\text{sec}$ and adult JE was 0.982 ± 0.253 (SD) $\times 10^{-3} \text{ mm}^2/\text{sec}$.

Conclusion The majority of the JE patient shows abnormal signal alterations in bilateral thalami and substantia nigra. Diffusion-weighted imaging with ADC mapping helps in evaluating the stage of the JE. No statistical significance of the various conventional MRI findings was found between the pediatric JE and adult JE.

Introduction

Japanese B encephalitis (JE) is one of the mosquito-borne flaviviral infections that is transmitted through mosquito bites. JE is one of the common causes of acute encephalitis syndrome (AES). JE is a common health problem in countries like Japan, Korea, and India.¹ Recurrent outbreak of JE are reported annually, between the month of July and October from the districts of upper Assam of Northeast India.² JE had an estimated annual incidence of 30,000 to 50,000 and had 15,000 deaths per year in children below 15 years in India.³⁻⁵

In the endemic area, children below 15 years of age are more vulnerable and even more prone in 3 to 6 years of age.⁵

The majority of the infection is asymptomatic, with only 20 to 30% of patients presenting with overt symptoms or fatality.⁶ About 30 to 50% of survivors of acute severe JE had long-term abnormal neurological, behavioral, cognitive sequelae, and extrapyramidal syndrome, especially in children.^{3,6} The case fatality rate of acute severe symptomatic JE patients increases up to 30%.⁶

The JE lesions are commonly observed in thalami, substantia nigra, and basal ganglia with less involvement of brain stem, cerebral cortices, cerebellum, cerebral white matters, and spinal cord.^{4,7} However, the distribution, extent, number of involved sites, and sizes of these lesions might vary in the pediatric JE and adult JE.

Moreover, T2 weighted image (T2WI) hyperintensities in thalami have high specificity for JE in the endemic area.^{4,8} The most common differentials of thalamic T2WI hyperintensities include hypoxic-ischemic encephalopathy, Wernicke's encephalopathy, herpes encephalitis, Wilson's disease, deep vein thrombosis, artery of Percheron infarct, Creutzfeldt-Jakob disease (CJD), and other flavivirus encephalitis, such as, dengue encephalitis and West Nile encephalitis.⁹

Atypically, JE with temporal lobe dominance can be difficult to differentiate from herpes encephalitis and autoimmune encephalitis.¹⁰ Autoimmune encephalitis most commonly affects bilateral mesial temporal lobes and limbic systems with less involvement of lateral temporal lobe and insular cortices with typical presentation of gradual short-term memory loss and mental status changes without acute encephalitic symptoms.¹¹ Typical involvement

of medial temporal lobes, insular cortex, and orbitofrontal lobes was observed in herpes simplex virus 1. The posterior medial thalamus is commonly involved in JE whereas the anterior lateral thalamus is involved in Wilson disease.¹² JE can also cause deep venous sinus thrombosis in children.^{13,14} Furthermore, the bilateral thalamic T2W hyperintensities in deep vein thrombosis is usually associated with hemorrhages.¹⁵ The typical magnetic resonance imaging (MRI) findings of CJD show symmetrical bilateral posterior thalamic T2W hyperintensities giving "pulvinar sign" and dorsomedial thalamic nuclei hyperintensities giving "hockey stick sign."^{16,17} Also, lack of fever and other acute encephalic symptoms in CJD helps to differentiate it from acute JE.^{16,17}

The distribution, extension, number of involved sites, and sizes of these lesions might vary in pediatric and adult JE. These differences in MRI abnormalities in pediatric and adult JE might help in neuroradiological diagnosis, and possibly have implications on treatment plans.

This study was performed to evaluate the conventional MRI findings in JE and to find out any difference between pediatric and adult JE.

Materials and Methods

A retrospective cross-sectional study was conducted at our institution on serologically positive 54 JE patients presented with acute encephalitic symptoms between April 2016 and October 2019. This retrospective study was approved by the institutional ethics review committee.

MRI Protocols

The patients underwent an MRI scan of the brain, using a 1.5T MR scanner, Siemens Magnetom Avanto (Siemens Medical Systems, Erlangen, Germany). Conventional MRI sequences protocol includes axial T1WI, T2WI, fluid-attenuated inversion recovery (FLAIR), diffusion-weighted imaging (DWI), and susceptibility-weighted imaging (SWI) sequences followed by sagittal T1WI and coronal T2WI sequences. Post-gadolinium T1WI sequences were obtained in all three planes. The parameters of the various MRI sequences used are shown in ►Table 1.

Table 1 Showing parameters used in various conventional MRI sequences

MRI sequence	TE (ms)	TR (ms)	Matrix	Field of view (FOV)	Slice thickness (mm)	Flip angle	Others
T2W axial	90–110	3,800–6,000	512	220–250	5	150°	
T1W axial	8–10	500–600	512	220–250	5	150°	
FLAIR axial	90–100	9,000	512	220–250	5	150°	TI = 2,500 ms
DWI axial	90–110	3,000–4,000	128	220–250	5	90°	b-value = 0 and 1,000 sec/mm ²
SWI axial	40	50–60	256	220–250	2	15°	
T1W sagittal	8–10	500–600	256	220–250	4	90°	
T2W coronal	80–95	4,000–6,000	512	220–250	4	150°	

Abbreviations: DWI, diffusion-weighted imaging; FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging; SWI, susceptibility weighted imaging; TE, time of echo; TI, time of inversion; TR, repetition time.

Serological Test

Confirmation of JE was established by immunoglobulin M antibodies positivity to the JE virus in cerebrospinal fluid and serum samples by enzyme-linked immunosorbent assay technique.

Apparent Diffusion Coefficient Calculation

The apparent diffusion coefficient (ADC) values were measured independently by two radiologists and the results were obtained from the mean ADC values. Calculation of the mean ADC values was done by placing either round or elliptical regions of interest (ROIs). We measured the mean ADC value in the operating system console using three uniform size ROIs (with area: maximum 50 mm² and minimum 10 mm²) placed in the ADC map image of $b = 1,000$ sec/mm², and the mean ADC value was calculated for statistical analysis.

Statistical Analysis

All statistical analysis was performed using Statistical Package for Social Science (SPSS, version 16). A nonparametric Wilcoxon rank test was performed to find out the difference between group 1 and group 2 of JE patients. An independent sample Student's *t*-test was used to compare the mean ADC values between pediatric and adult JE patients. Statistical significance was considered when the *p*-value was ≤ 0.05 .

Results

Of the 54 JE patients of our study, 31 were males and 23 were females with a mean age of 22.9 ± 1.9 (standard deviation [SD]) years. The age range was 7 months to 73 years. Patients aged less than 18 years were categorized into pediatric JE ($n = 32$) group and those above 18 years into adult JE ($n = 22$) group. JE patients with duration of onset of acute encephalitic symptoms like high fever, headache, neck stiffness, and altered mental status less than 15 days up to the day of MRI scan were categorized into group 1 JE ($n = 16$) and those more than 15 days into group 2 JE ($n = 38$). The mean day of MRI examination from the time of onset of acute encephalitic symptoms was 14.3 ± 4.6 (SD). Group 1 JE comprised of 16 patients (29.6%) and group 2 JE comprised of 38 patients (73.4%).

Diffusion restriction with low ADC value means the true diffusion restriction in acute JE patients. It indicates that group 1 JE patients (►Figs. 1 and 2) were imaged at the stage of perivascular cuffing leading to ischemic and cytotoxic edema, which resulted in true diffusion restriction. Statistical significance was found between the duration of symptoms onset up to the day of MRI examination and mean ADC values of JE lesions with *p*-value < 0.0005 by using nonparametric two related samples Wilcoxon signed rank test. The various brain MRI findings of JE are summarized in ►Table 2.

Fig. 1 Cranial magnetic resonance imaging was done on day 9 on 28 female patients with acute encephalitic symptoms. Axial T2WI (A and B) and sagittal T2WI (C) images showing asymmetrical hyperintensities in bilateral substantia nigra and thalami with the affection of the right insular cortex. Axial fluid-attenuated inversion recovery image (D) also showing the abnormalities. Axial diffusion-weighted imaging (E) and apparent diffusion coefficient (ADC) map (F) images showing diffusion restrictions in the affected regions with low ADC value (arrow).

Fig. 2 Cranial magnetic resonance imaging was done on day 18 on an 11 years old female with fever and headache. Axial T2WI (A and B) and axial fluid-attenuated inversion recovery (C) images showing hyperintensities in bilateral thalami, substantia nigra, and left caudate head along with a central T2 hyperintense and peripheral hypointense cyst in the left frontal lobe with perifocal edema. Axial T1W postcontrast image (D) showing rim enhancement of the left frontal lobe neurocysticercosis lesion (arrow). Axial diffusion-weighted imaging (E) and apparent diffusion coefficient map (F) images showing facilitated diffusion in the thalami (black arrow).

Fig. 3 Cranial magnetic resonance imaging was done on day 6 on a 7-month-old male baby with acute encephalitic symptoms. Axial T2WI (A and B) and coronal T2WI (C) images showing hyperintensities in bilateral putamen, caudate nuclei, and substantia nigra without involvement of thalami. Axial T1WI image (D) showing patchy T1 hyperintense bleeds in the bilateral putamen. Axial diffusion-weighted imaging (E) and apparent diffusion coefficient (ADC) map (F) images showing diffusion restrictions with low ADC value.

Abbreviations: JE, Japanese encephalitis; MRI, magnetic resonance imaging; NCC, neurocysticercosis.

Fig. 4 Cranial magnetic resonance imaging was done on day 5 on a 9 years old male with headache and fever. Axial T2WI images (A–C) showing hyperintensities in basilar pons, bilateral substantia nigra, caudate, and lentiform nuclei. Axial fluid-attenuated inversion recovery images (D–F) showing hyperintensities in the basilar portion of pons (arrow), bilateral caudate, and lentiform nuclei.

Pediatric JE patients had mean ADC value of 0.907 ± 0.336 (SD) $\times 10^{-3} \text{ mm}^2/\text{s}$ and adult JE had 0.982 ± 0.253 (SD) $\times 10^{-3} \text{ mm}^2/\text{s}$. No difference was found between the mean ADC value of pediatric JE and adult JE patients by using an independent sample Student's *t*-test (*p*-value of 0.388). Group 1 JE had a mean ADC value of 0.563 ± 0.109 (SD) $\times 10^{-3} \text{ mm}^2/\text{s}$ and group 2 JE had 0.095 ± 0.206 (SD) $\times 10^{-3} \text{ mm}^2/\text{s}$ with a significant difference between these two groups by using the Wilcoxon signed-rank test (*p*-value < 0.0005).

T2WI and FLAIR thalamic hyperintensities were demonstrated in 53 patients (98.1%), bilaterally asymmetrical in 48 patients (88.9%) (►Figs. 1 and 2), bilaterally symmetrical in 4 patients (7.4%), and unilateral in another 1 patient (1.9%). Bilateral substantia nigra involvement was observed in 44 patients (81.5%), bilaterally asymmetrical in 30 patients (59.3%) (►Fig. 1), and bilaterally symmetrical in 12 patients (22.2%) (►Fig. 2). Hippocampal involvement was observed in 14 patients (26%), unilateral in 9 patients (16.7%), and bilateral in 5 patients (9.3%). Total hippocampal involvement was observed in 4 patients (7.4%), hippocampal head and body involvement in 7 patients (13%), and only tail involvement in 3 patients (5.6%). Caudate nuclei involvement was observed in 22 patients (40.7%), bilaterally symmetrical in 8 patients (14.8%) (►Fig. 3), bilaterally asymmetrical in 8 patients (14.8%), and unilateral in 6 patients (11.1%) (►Fig. 2). Lentiform nuclei involvement was observed in 29 patients (53.7%), bilaterally asymmetrical

in 15 patients (27.8%), bilaterally symmetrical in 4 patients (7.4%) (►Figs. 3 and 4), and unilateral in 10 patients (18.5%). Insular cortex involvement was observed in 2 patients (3.8%) (►Fig. 1). Cerebral cortex involvement was observed in 21 patients (38.9%), with single cerebral hemispheric involvement observed in 13 patients (24.1%) (►Fig. 5) and bilateral cerebral hemispheric involvement in 8 patients (14.8%).

Cerebral cortex involvement in more than one lobe of the cerebral hemisphere was observed in 9 patients (16.7%) (►Fig. 5) with only frontal lobe cortical involvement observed in another 8 patients (14.8%). Involvement of pons was observed in 5 patients (9.3%) (►Fig. 4) and medulla oblongata involvement in 3 patients (5.6%). On SWI, thalamic microbleeds were observed in 2 JE patients (3.7%).

JE coinfection with neurocysticercosis (NCC) was observed in 12 patients (22.2%) (►Fig. 2), with the involvement of one cerebral hemisphere in 6 patients (11.1%) and bilateral cerebral hemispheres in another 6 patients (11.1%).

Discussion

Abnormal T2 and FLAIR hyperintensities of typical JE may be observed in thalami,^{4,7,18,19} substantia nigra, basal ganglia,^{19–21} hippocampus, and pons and less commonly in the cortical and subcortical regions^{4,8,22} and cerebellar

Fig. 5 Cranial magnetic resonance imaging was done on day 7 on a 5-year-old boy with acute encephalitic symptoms. Axial T2WI (A) image showing hyperintensities in the bilateral thalami. Axial fluid-attenuated inversion recovery (FLAIR) images (B and C) showing hyperintensities in the cortical and subcortical regions of right superior frontoparietal lobes. Axial diffusion-weighted imaging (D) showing diffusion restrictions in the affected cortices. Apparent diffusion coefficient (ADC) map (E and F) images showing pronounced hypointense signals of low ADC value in the subcortical white matters of right superior frontoparietal lobes and overlying cortices (arrow).

hemisphere. The conventional MRI sequences like T2WI, FLAIR, and DWI can detect most of the abnormalities in JE patients.²² However, in newborns and infants, DWI can detect acute encephalitic lesions, much earlier than conventional T2WI and FLAIR sequences.²³ This is because of more water content in the immature brain leading to problems with achieving conspicuity between the normal brain and encephalitic lesions in T2WI and FLAIR images.²³ DWI can detect cytotoxic edema which is the earliest sign of any encephalitic process. Thus, DWI is more sensitive in early cases of JE but less sensitive in late cases of JE.²³ Consequently, DWI can detect brain parenchymal changes in JE within few hours or 1 day before any demonstrable changes are observed in T2WI and FLAIR images.²³ Acute stage of JE shows diffusion restriction with low ADC value.²⁴ ADC value gradually increases after the late acute stage and remains higher in the chronic stage.²⁴

Arahata et al²⁵ demonstrated the successive changes in DWI on MRI in the thalamus ranging from spotty appearance to uniform pattern and also emphasized that the JE virus may initially affect the unilateral thalamus with subsequent involvement of the other side.

Another study showed progressive T2 and FLAIR hyperintensities in the thalami in the early stage of the disease.²⁶ With the subsequent progression of JE, the T2 shine-through effect is observed in the lesions in the subacute stage, with gradually increasing ADC value and fogging of bright signals on

diffusion-weighted images. In the chronic stage, the affected areas showed gliosis, cavitations, and atrophy.²⁵ The resolution of T2 and FLAIR hyperintensities usually occurred within 1 to 3 months of clinical recovery but may persist for a longer course, sometimes even up to 1 year.⁸ A repeat follow-up MRI, should usually be done after 1 to 3 months of clinical recovery of JE patient.⁸

MRI plays an important role in the radiological diagnosis of JE, by detecting the distribution, extension, and status of the parenchymal lesions (whether acute, subacute, or chronic), and excluding other AES-induced encephalitis. Even though overlap imaging features of herpes encephalitis, autoimmune encephalitis, and temporal lobe dominant JE are there, but these can be differentiated by MRI by observing the simultaneously altered signal intensities in the thalami, substantia nigra, and hippocampus in JE patients.^{7,10,27,28}

In our study group, substantia nigra affection was commonly observed in 81.5% (44/54) patients as compared with the previous literature from India.^{18,29-31} **Table 2** shows the review literature on MRI findings of JE from India in the last decade. In our study group, medial temporal lobe involvement with dominant hippocampal affection was observed in 26% (14/54) patients. Handique et al²⁸ found hippocampal involvement in 11 out of 62 JE patients (17.7%).

The characteristic temporal lobe involvement pattern which is seen in JE typically affects the hippocampus,

Table 3 Summary of magnetic resonance imaging findings in common flavivirus encephalitis

Type	Sites of affection	Cranial MRI findings	Associated findings
Japanese encephalitis	<ul style="list-style-type: none"> - Thalami and substantia nigra are commonly involved - Basal ganglia, pons, cerebral cortex, and cerebellum are sometime involved 	<ul style="list-style-type: none"> - T2 and FLAIR hyperintensities in the affected areas with diffusion restricted in early acute stage and facilitated diffusion in subacute stage - Rarely hemorrhage can be seen in JE 	<ul style="list-style-type: none"> - Neurocysticercosis coinfection - Rarely dengue coinfection can occur - Rarely may associated with CVST
Dengue encephalitis	<ul style="list-style-type: none"> - Thalami and basal ganglia are commonly affected - Pons, medulla, cerebellum, corpus callosum, and cerebral cortex can be involved 	<ul style="list-style-type: none"> - T2 and FLAIR hyperintensities with restricted diffusion - Parenchymal or extra-axial bleed can be seen and which is more common in dengue encephalitis than JE - Diffuse cerebral edema may be seen 	<ul style="list-style-type: none"> - Cerebellitis is more common - Cortical laminar necrosis
West Nile encephalitis	<ul style="list-style-type: none"> - Brain stem, basal ganglia, and corona radiata commonly affected - Thalami, cerebral cortex, and white matters may be involved 	<ul style="list-style-type: none"> - Isolated diffusion restrictions in posterior limb of internal capsule/ corona radiata - T2 and FLAIR hyperintensities in brain stem, basal ganglia, thalami, etc. - Meningitis changes seen 	<ul style="list-style-type: none"> - Enhancement of cauda equina and lumbosacral nerve roots - Spinal cord T2 hyperintensities can be seen
Tick-borne encephalitis	<ul style="list-style-type: none"> - Cerebellum commonly affected - Thalami, basal ganglia, and anterior horn cell of spinal cord may be affected 	<ul style="list-style-type: none"> - Leptomenigitis along cerebellar folia and basal cisterns - T2 and FLAIR hyperintensities in thalami, basal ganglia, and cerebellum

Abbreviations: CVST, cerebral venous sinus thrombosis; FLAIR, fluid-attenuated inversion recovery; JE, Japanese encephalitis; MRI, magnetic resonance imaging.

especially its body and tail with sparing of the rest of the temporal lobe.

Previous literature showed a variable association of JE with NCC.^{32,33} Handique et al³² found JE with NCC coinfection in 19.3% (12/62) patients from Northeast India. In our study group, JE coinfection with NCC was found in 22.2% (12/54) patients. Moreover, five of these patients showed more confluent T2 hyperintensities in thalami, basal ganglia, and cerebral cortices in the NCC involved hemisphere. Furthermore, out of these 12 patients, poor clinical and neurological recovery was observed in 5 patients, with partial recovery in another 4 patients, and complete recovery in the rest of the 3 patients, on a follow-up period ranging from 12 to 18 months.

Sivamani et al³⁴ reported JE coinfection with dengue virus infection in the same population as the transmission of both viruses intensifies during the rainy season. Dengue encephalitis most commonly showed abnormal T2 and FLAIR hyperintensities with restricted diffusions in thalami and basal ganglia. Less commonly pons, medulla, cerebellum, corpus callosum, and cerebral cortex can also be involved in dengue.³⁵ Intraparenchymal or extra-axial bleed is more common in dengue encephalitis than JE. Cerebellitis may also be associated with dengue encephalitis.³⁵ ►**Table 3**

summarizes the MR imaging findings in common flavivirus encephalitis.

JE with cerebral venous sinus thrombosis (CVST) is a rare occurrence with very few cases reports in the literature.³⁶⁻³⁸ In our study group, no CVST was detected.

Our study observed a higher incidence of multifocal lesions with greater involvement of cerebral cortices in pediatric JE compared with adult JE patients. However, no significant difference was observed between the cranial MRI findings in pediatric and adult JE patients (►**Table 2**).

The lack of adequate statistical power in our observations to discriminate differences in MRI findings between pediatric and adult JE is most probably due to the small sample size. Nevertheless, these differences in the MRI findings between the pediatric and adult JE may be clinically significant in predicting the clinical outcome and neurological recovery, and might help in treatment planning. Therefore, a larger prospective study to confirm these findings is warranted in the future.

Conclusion

Pediatric JE has a more severe form of encephalitis than adult JE with a poorer prognosis. No statistically significant difference

in various brain MRI findings was observed between pediatric JE and adult JE. But a higher incidence of multifocal parenchymal lesions with greater involvement of cerebral cortices in pediatric JE as compared to adult JE was observed in our study group.

Conflict of Interest

None declared.
