The recent development of a humanized, bi-specific, and monoclonal antibody mimicking the function of activated factor VIII was a revolution in the management of patients suffering from severe hemophilia A with inhibitors.¹ The phase III randomized studies have shown a more efficient prophylaxis of this subcutaneous administered drug in these patients compared with recombinant FVIIa (rFVIIa) and activated prothrombin complex concentrates (aPCC).^{2,3} Nonetheless, there are “real life” matters that need to be explored in this new era of managing hemophilia patients, such as surgery management under emicizumab, especially in children.^{4–6} Here, we report the first case, to our knowledge, of major orthopedic surgery managed with factor VIII infusions in a child with inhibitor receiving emicizumab.

Our patient is a 9-year-old boy with severe hemophilia A. He presented an inhibitor after the 10th exposed day with a factor VIII (FVIII) concentrate (historic peak: 412 BU/mL). Thereafter, he presented an important intracranial hemorrhage (subdural and intraparenchymal hematomas). The first treatment with rFVIIa (Novoseven, 90 µg/kg/2 h) and tranexamic acid was inefficient. It was therefore switched with aPCC (FEIBA 80 IU/kg/8 h) that was rapidly effective. He also presented some knees and left hip hemarthrosis responsible for arthropathies. Several attempts of immune tolerance induction through Port-a-Cath failed whatever the FVIII concentrate used, recombinant FVIII or plasma-derived FVIII. Because of an insufficient efficacy

of rFVIIa for totally stopping some bleeding events, a prophylaxis with aPCC was performed with daily infusion of 80 IU/kg. Given the cumbersome nature of this treatment, emicizumab (Hemlibra) was introduced instead of aPCC in December 2018. Emicizumab was started with 3 mg/kg/week for 4 weeks and then adapted to 1.5 mg/kg/week. The boy had no more bleeding including clinically evident hemarthrosis. However, the left hip arthropathy worsened with aggravation of limping and pain leading to the use of a wheelchair. Hip X-ray showed an osteonecrosis of the left femoral head requiring a femoral varization osteotomy that was planned in June 2020. Because the inhibitor titer was low at 2 BU/mL, rFVIII-Fc (Elocta) was administered to normalize the coagulation during the surgery. A rFVIII-Fc bolus with 6,000 IU (150 IU/kg) was initially administered, followed by a continuous infusion 12 IU/kg/h (→ **Fig. 1A**). The emicizumab treatment was continued (1.5 mg/kg/week).

This complex surgery performed on rFVIII-Fc required a close monitoring with frequent FVIII:C measures to adjust rFVIII-Fc administrations. All FVIII:C levels were measured with a chromogenic method (STA-R Max3 analyzer ; Trini-CHROM FVIII:C reagent – Stago) by using bovine coagulation factors X and IXa that do not interfere with emicizumab.^{7–9} In same plasma samples, thrombin generation assays (TGA) were performed by using low concentration of tissue factor (1 pM) as suggested for the TGA in hemophilia A patients.¹⁰

rFVIIa was ruled out because it was often only partially effective for this patient. We show here that, as for some adults reported to date, major surgeries can be safely managed with FVIII concentrates in children with severe hemophilia A with inhibitor while receiving emicizumab. This dual treatment could also be applicable without an inhibitor at the doses usually administered.¹⁵ In our patient, the FVIII:C chromogenic assay appeared to be a reliable tool for peri-surgical monitoring in children despite concomitant treatment with emicizumab as it was proposed.^{8,9} TGA with low TF concentration performed in parallel to FVIII:C measures could be helpful.⁹ However, our results did not show a perfect correlation between TGA's parameters and normalized FVIII levels. The TGA with these conditions is so not enough reliable for the monitoring of emicizumab treatments and need further adjustments. Finally, it was rapidly observed that maintaining the prophylaxis with emicizumab reduces the duration of post-surgical treatment in major orthopaedic surgeries.¹³ Indeed, for our patient, as already reported for adults receiving emicizumab, FVIII or rFVIIa injections were only necessary until the 7th day post-surgery. Thereafter, prevention with emicizumab alone was sufficient to protect against late bleeding during rehabilitation.

Authors' Contributions

All authors made substantial contributions to the conception or design of the work, the acquisition, analysis, interpretation of data, as well as drafting or revising the work critically and giving final approval of the version to be published.
