Abstract

Keywords

- Ewing's sarcoma
- musculoskeletal soft tissue
- oncology
- pediatric
- rhabdomyosarcoma

Extraosseous Ewing's sarcoma (EES), first described in 1969, is a malignant mesenchymal tumor just like its intraosseous counterpart. Although Ewing's sarcomas are common bone tumors in young children, EESs are rarer and more commonly found in older children/adults, often carrying a poorer prognosis. We discuss the multimodality imaging features of EES and the differential diagnosis of an aggressive appearing mass in proximity to skeletal structures, with pathologic correlates. This review highlights the need to recognize the variability of radiologic findings in EES such as the presence of hemorrhage, rich vascularity, and cystic or necrotic regions and its imaging similarity to other neoplasms that are closely related pathologically.

Introduction

Ewing's sarcoma was first described in 1921 by James Ewing as an osteolytic bone tumor composed of malignant small round cells.^{1,2} Extraosseous Ewing's sarcoma (EES) was first described in 1969³; it is a malignant mesenchymal tumor much rarer than its intraosseous counterpart. The few case series and reports of EES that have been published in English literature in the last decade have been listed in ►Table 1.^{4–8} There are a few malignant and benign entities that may mimic an EES on imaging and therefore, it is essential that radiologists be familiar with this entity and its radiological aspects to help render an accurate diagnosis. This article depicts the imaging appearances and findings of five EESs in various anatomical sites, involving multiple

modalities (►Table 2). Pathologic features of EESs are discussed. This review is written with the intent to enhance the existing knowledge base/awareness among radiologists of this rare entity.

Discussion

Ewing's sarcomas are common bone tumors in children.⁹ EES is rarer, more commonly found in older children/adults, and often carries a poorer prognosis.^{5,10} EES has increasingly been reported from diverse sites whose origin has been attributed to ectopic neural and neuroectodermal proliferations. Genetic studies have suggested that EESs are in the same family as primitive neuroectodermal (PNET) tumors. Furthermore, genetic studies have demonstrated reciprocal

Table 2 Patient demographics and location of tumors

Age (y)	Sex	Location	Imaging characteristics
1	Male	Occipital scalp (►Fig. 1)	Heterogeneous subcutaneous soft tissue lesion without bony invasion on computed tomography
7	Female	Posterior neck (►Fig. 2)	Subcutaneous soft tissue lesion, hypoechoic with hyperechoic foci and internal vascularity on Doppler
26	Female	Left thigh (►Fig. 3)	Predominantly solid with heterogeneous echogenicity and cystic areas/internal vascularity. Mildly T1 and T2 hyperintense solid mass with peripheral enhancement and central necrosis
20	Female	Right inguinal (►Fig. 4)	Soft tissue mass with heterogeneous increased multicystic T2 hyperintense mass with septations. Heterogeneous enhancement with areas of cystic change/necrosis
19	Male	Right shoulder (►Fig. 5)	T1 isointense and T2 hyperintense solid mass that diffusely enhances and contains a few flow voids representing vessels

translocation of t(11; 22)(q24; q12) in approximately 95% of patients, with the remainder demonstrating t(21; 22) (q22; q12) translocation.^{11,12} Generally, these tumors are commonly seen in the paravertebral regions or in the deep soft tissues of the extremities, with lower extremities having a higher propensity than upper extremities.⁹ Patients with EES often note a rapidly growing soft-tissue mass, with about one-third being painful secondary to compression of adjacent structures. They often present in the second decade of life. There is a mild male predominance and predilection for Caucasians. There has not been any evidence of familial or environmental influence.¹¹⁻¹⁴

Radiographs may demonstrate a nonspecific soft-tissue mass in proximity to a bone without gross osseous involvement.^{9,15,16} Computed tomography (CT) usually shows a soft tissue mass with similar attenuation as skeletal muscle (►Fig. 1).^{9,15} Adjacent bone involvement is uncommon (►Fig. 1).^{9,15} Calcification is exceedingly rare^{9,15} and this feature was a consistent imaging appearance in our patients.

Fig. 1 (A, B) Axial CT (A) shows a circumscribed homogeneous subcutaneous mass in the right occipital scalp (white arrows). Bone windows (B) shows no erosion of the calvarium by the mass (white arrows). CT, computed tomography.

Fig. 2 (A, B) Sagittal ultrasound images (A, B) show a circumscribed solid hypoechoic mass (white arrows) with small echogenic striations and mild internal vascularity (arrowheads) in the subcutaneous soft tissue of the right posterior neck.

Sonographic findings are variable and nonspecific, and often demonstrate a hypoechoic, heterogeneous mass with internal vascularity (►Fig. 2).^{9,15} Cystic change and necrosis may be seen (►Figs. 3 and 4).^{9,15}

Findings on magnetic resonance imaging (MRI) include a mass with signal intensity similar to skeletal muscle on T1-weighted imaging (►Figs. 5 and 6).^{9,15} Internal areas of hemorrhage may be seen as high T1 signal (►Fig. 3).^{9,15} On T2-weighted images, the mass often demonstrates a heterogeneous intermediate to hyperintense signal. High T2 signal areas representing foci of cystic or necrotic changes are common (►Fig. 4).^{9,15} On postcontrast images, there is often heterogeneous enhancement (►Figs 3–6). High-flow vascular channels or flow voids may also be seen (►Fig. 5) which is extremely common, although not unique to EES.^{9,15} Some of

these masses may be quite complex, having undergone cystic degeneration/necrosis, and may contain internal septations (►Fig. 4).^{9,15} Fluid-fluid levels may also be observed.^{13,15,17,18}

Fig. 3 (A–D) Sagittal ultrasound image (A) of the left proximal thigh shows a mass with heterogeneous echogenicity (white arrows) which is predominantly solid with some areas of cystic change/necrosis. Internal vascularity (white arrowheads) is seen with Doppler imaging. The axial T1 (B), T2 (C), and postcontrast (D) MRI images of the proximal thigh show a mass with mixed T1 and T2 signal and thick inhomogeneous peripheral enhancement with areas of central necrosis (white arrows). MRI, magnetic resonance imaging.

On gross pathological specimen, EES often appears gray-yellow or gray-tan with lobulations and a soft texture.⁹ Histopathology confirms EES via monotonous proliferation of small blue round cells solidly packed with intracellular glycogen which may indent nuclei (►Figs. 7 and 8).⁹ Cystic/necrotic regions demonstrating rich vascularity, and areas of hemorrhage are often present. Membrane staining is almost always positive for CD99 (►Figs. 7 and 8).^{19,20} Histologic staining for FLI1, demonstrating t(11; 22), will provide definitive diagnosis (►Fig. 8).¹⁹

Treatment often involves neoadjuvant chemotherapy typically with ifosfamide and etoposide followed by a combination of surgical excision and radiation therapy.^{4,5,21–25} Increased tumor burden and distant metastasis at presentation are associated with a poor overall survival.⁴ The 5-year survival for patients with localized disease is around 60% and 40% for patients with metastatic disease.²⁶

Differential Diagnosis

Differential considerations of EES mainly include rhabdomyosarcoma and synovial sarcoma (►Table 3).

Neuroblastoma and lymphoma are less common considerations. Benign entities such as a venous malformation, especially the microcystic type, soft-tissue abscesses, and hematomas can also mimic a soft tissue tumor. Rare tumors, such as extraosseous mesenchymal chondrosarcomas, may also be included in the differential for an EES.

Rhabdomyosarcoma is the most common soft tissue malignancy in children and may be painless though rapidly growing. CT will demonstrate a soft-tissue density (►Fig. 9) with heterogeneous enhancement ± adjacent bony

Fig. 4 (A–F) Sonographic image (A) demonstrates a predominantly hypoechoic mass (white arrows) in the right groin with internal septations. Axial CT (B) demonstrates a heterogeneous well-circumscribed soft-tissue mass (white arrows) in the right groin without evidence of calcification. Axial T2 fat sat (C), T1 (D), postcontrast axial T1 (E), and coronal (F) MRI images demonstrate a complex predominantly multicystic mass, in the right groin (white arrow) with a thin rim of peripheral enhancement and an eccentric inhomogeneous soft tissue component at its superior aspect (white arrowheads). CT, computed tomography; MRI, magnetic resonance imaging.

Fig. 5 (A–D) Axial T1 (A), T2 (B), T2 fat sat (C) postcontrast T1 fat sat (D), MRI images demonstrate a T1 isointense and T2 hyperintense enhancing mass (white arrows) within the right anterior deltoid muscle. Flow voids representing vessels (arrowhead in B). MRI, magnetic resonance imaging.

Fig. 6 (A–D) Axial STIR (A), axial T1 (B), sagittal and axial (C, D) postcontrast MRI images demonstrate a T2 hyperintense and T1 isointense mass with heterogeneous enhancement and areas of cystic change/necrosis (black arrowheads) within the left biceps muscle (white arrows). MRI, magnetic resonance imaging.

destruction.²⁷ MRI demonstrates T1 isointensity to muscle $\pm$ areas of hemorrhage and T2 hyperintensity to muscle associated with avid enhancement.²⁸ There may be prominent flow voids (in alveolar subtype). Embryonal, alveolar, and pleomorphic histologic subtypes, all show skeletal muscle differentiation which is key to histopathological diagnosis ($\blacktriangleright$ Fig. 9).^{27–29}

Fig. 7 (A–C) Histopathological images from patient in Fig. 5: Low (A) and high (B) power views of the classic round blue cell look that is seen with neuroblastoma, rhabdomyosarcoma, Ewing's sarcoma, and lymphoma. Immunohistochemical stain for CD-99 (C), which is a Beta 2 Microglobulin on the outside of the cell gives the brown outline. In a mass CD-99 is not specific for Ewing's sarcoma but is highly characteristic.

Fig. 8 (A–C) Histopathological images from patient in Fig. 6: High power view (A) of the small round blue cell tumor. The CD99 staining (B) demonstrates a brown rim around the cells, highly characteristic of, though not specific for, Ewing sarcoma. The FLI1 (C) is a new immunohistochemical stain that looks for the chromosome 11–22 translocation (EMS-FLI1) which is characteristic of Ewing's sarcoma and stains the nucleus brown as seen in this patient.

Synovial sarcomas are the most common nonrhabdomyosarcomatous childhood malignancies of the lower extremities.³⁰ These slow growing masses have predilection for juxta-articular regions.^{30,31} CT examination will demonstrate a heterogeneous soft-tissue mass with or without calcifications ($\blacktriangleright$ Fig. 10). MRI demonstrates a mass, generally isointense to muscle on T1-weighted imaging, with heterogeneous and hyperintense T2 signal from necrosis, areas of hemorrhage, and bands of fibrosis. The combination of largely cystic areas and prominent hemorrhagic foci often creates a “bowl of grapes appearance.”³⁰ Although the poorly differentiated subtype is histologically similar to EES, monophasic

Table 3 Differential diagnosis for Extraosseous Ewing's sarcoma

Tumor	Age (peak)	Sex	Location	Imaging
Rhabdomyosarcoma	First decade	Slight male predilection	Anywhere in the body. The alveolar and pleomorphic variants having a predilection for extremities	Heterogeneous magnetic resonance imaging (MRI) signal intensity and enhancement. Flow voids. Bone involvement in 25%
Synovial sarcoma	Third decade of life	Female predilection	Juxta-articular regions	"Bowl of grapes" and "triple sign" appearance on MRI from areas of necrosis and hemorrhage. Calcification in 30% of patients.
Neuroblastoma	One	No sex predilection	Adrenal and paravertebral	Necrosis or hemorrhage, and calcifications are common. MRI demonstrates high and low T1 and T2 signal, related to calcification, hemorrhage, and necrosis.
Extraosseous mesenchymal chondrosarcoma	Second to third decade.	Female predilection	Head and neck	Central or eccentric mineralization. MRI variable low signal mineralization with T2 hyperintensity and intense heterogeneous enhancement
Venous malformation	Any age	No sex predilection	No site predilection	Highly vascular lesion with thrombus, or phlebolith, on imaging

Fig. 9 (A–C) Axial CT image (A) demonstrates a left axillary mass (white arrow). Hematoxylin and eosin magnification $\times 400$ specimen (B) demonstrating skeletal muscle differentiation (black arrow). Rhabdomyoblasts highlighted by desmin stain (C). CT, computed tomography.

subtype reveals uniform atypical spindle cells, while biphasic subtypes have an epithelial element ($\rightarrow$ Fig. 10).³² "Synovial" is a misnomer, as these tumors are not derived from synovium. Cytogenetic studies show translocation of (x; 18).^{30,32–35}

Outside of the adrenal gland, neuroblastomas (NBLs) are often paravertebral in location but in a younger demographic than EES.^{36,37} Laboratory assessment will commonly show elevated urinary catecholamine levels.³⁶ Bony metastases are common and may be the presenting finding.³⁶ On ultrasound, NBLs are heterogeneous solid lesions, mostly echogenic.³⁶ The masses may appear heterogeneous from necrosis or hemorrhage, and calcifications are common.³⁶ CT or MRI can accurately assess the location and the size of the primary tumor

Fig. 10 (A, B) Axial CT (A) demonstrates a soft tissue mass (white arrow) in the anterior right upper thorax extending between the ribs. Hematoxylin and eosin magnification $\times 160$ (B) shows short, uniform, moderately atypical spindle cells, consistent with monophasic synovial sarcoma. CT, computed tomography.

and identify vascular encasement which determines tumor resectability.^{36,37} Coarse, finely stippled, or curvilinear calcifications are seen in 85% of the neuroblastomas.³⁶ MRI demonstrates high and low signal on T1 and T2 imaging, related to calcification, hemorrhage, and necrosis.^{36,38} Microscopic features include immature, undifferentiated sympathetic cells.^{39–42}

Lymphomas are differentiated from EES via identification of lymph node involvement; EES rarely involves lymph nodes.^{43–45}

Extraosseous mesenchymal chondrosarcomas are painless, slowly growing masses with chondroid matrix ($\rightarrow$ Fig. 11). The lesion is extremely rare in patients younger than 20 years of age. On CT, a soft tissue mass with similar attenuation to muscle is demonstrated with either central or eccentric mineralization.^{46,47} Necrosis may be present, and enhancement is heterogeneous. MRI findings include a soft-tissue mass containing variable low-signal mineralization with isointensity to muscle on T1-weighted imaging and hyperintensity on T2-weighted imaging and intense heterogeneous enhancement ($\rightarrow$ Fig. 11).⁴⁶ Histopathologic features include a biomorphic appearance with well-differentiated cartilage surrounded by sheets of closely packed undifferentiated cells. Stains are positive for S100, neuron-specific

Fig. 11 (A–C) Extra osseous mesenchymal chondrosarcoma of the left thigh. AP radiograph of the femur (A) showing a calcified mass (white arrow) in thigh. The mass (white arrow) is T1 isointense (B) with enhancement (white arrow) on the postcontrast images (C). AP, anteroposterior.

enolase, and Leu-7, and negative for actin, epithelial membrane antigen, and cytokeratin.^{47–51}

Benign entities including venous malformations, soft-tissue abscesses, and hematoma can be distinguished based on several key features. Rapidly growing venous malformations can be distinguished by identifying a highly vascular lesion with thrombus or phlebolith on imaging. Soft-tissue abscesses are often thick rimmed, with irregular peripheral enhancement, and the patient usually has systemic and local symptoms of infection. Hematomas may show dark signal on susceptibility weighted sequences due to presence of blood products.^{52–56}

Conclusion

EES should be considered in the differential diagnosis when a circumscribed, aggressive appearing mass is encountered in the lower extremities or paravertebral regions of an older child/adolescent. Features, like flow voids, T1 signal similar to muscle, proximity to bone without gross osseous involvement in the early stages, cystic changes/necrosis, and lack of calcification, are seen in EES and are helpful in narrowing the differential diagnosis.

Declaration of Patient Consent

The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.
