

Genes in Thoracic Aortic Aneurysms and Dissections – Do they Matter?

Translation and Integration of Research and Modern Genetic Techniques into Daily Clinical Practice

Abstract

Since the identification of the fibrillin-1 gene as the causal gene for Marfan syndrome, our knowledge of molecular genetics and the applicability of genetic testing in clinical practice have expanded dramatically. Several new syndromes related to thoracic aortic aneurysms and dissections (TAAD) have been described and the list of underlying genes in syndromal and nonsyndromal TAAD already includes more than 10 different genes and is rapidly expanding. Based on this knowledge, our insights into the underlying pathophysiology of TAAD have improved significantly, and new opportunities for targeted treatment have emerged. Clinicians involved in the care of TAAD patients require a basic knowledge of the disease entities and need to be informed on the applicability of genetic testing in their patients and families. Gene-tailored treatment and management is indeed no science fiction anymore and should now be considered as part of good clinical practice. We provide a systematic overview of genetic TAAD entities and practical recommendations for genetic testing and patient management.

Introduction

Over the past decade, expanding knowledge of the genetic basis of Thoracic Aortic Aneurysms and Dissections (TAAD) significantly improved our understanding of the pathogenesis of the disease and improved our ability for risk stratification and medical guidance of patients and their families. Strategies for molecular genetic testing have reached a hinge point with the introduction in routine diagnostics of high-throughput next generation sequencing techniques. It is therefore extremely important that clinicians in the field know the indications and limitations of molecular genetic testing. These will be reviewed in this manuscript.

Etiology and Classification

The etiology of TAAD is complex and heterogeneous. Degenerative aortic disease related to classical cardiovascular risk factors such as smoking, arterial hypertension, and hyperlipidemia are the main cause of TAAD in older patients. In younger patients with no risk factors, other causes, including genetic disease, should be considered. Genetic aneurysmal disease

can be categorized in three main groups: (i) inherited syndromes predisposing to early onset TAAD (<5% of all TAAD) such as Marfan syndrome (MFS), Loeys-Dietz syndrome (LDS), and Aneurysm-Osteoarthritis syndrome [1–3]; (ii) familial forms of TAAD (FTAAD - 20% of all TAAD) including patients with confirmed disease in first-degree relatives and evidence for an autosomal dominant inheritance pattern; these patients may sometimes present with associated cardiovascular lesions such as bicuspid aortic valve (BAV), patent ductus arteriosus (PDA), or cerebrovascular disease [4–6]; and (iii) isolated or sporadic forms of TAAD (80%) including patients with no family history or clinical features of a syndromic TAAD disorder. The latter two categories are the so-called nonsyndromic forms of TAAD as opposed to the syndromic forms of the first category.

Table 1 provides an overview of syndromic and nonsyndromic forms of TAAD with their corresponding genes and clinical features. Discriminative features are in bold.

The paradigm disease for genetically determined syndromic TAAD is Marfan syndrome (MFS), caused by mutations in the fibrillin-1 gene (*FBN1*). The diagnosis of MFS is based on the identification of clinical manifestations and may be supplemented with *FBN1* gene sequencing. Cardinal manifestations include dilatation of the aortic sinus, lens luxation, and a combination of additional features defined by the “systemic score.” Dilatation of more distal parts of the aorta occurs in a minority of MFS patients [7–9]; patients who underwent previous surgery of the ascending aorta seem at increased risk. A recent study from Mimoun and colleagues demonstrated that dissection in the descending part of the aorta may occur whatever the diameter of the ascending aorta [10].

In 2004, Mizuguchi et al. identified mutations in the Transforming Growth Factor Beta Receptor 2 gene (*TGFBR2*) in a large family and four additional probands presenting with aortic dilatation and variable additional clinical features reminiscent of a connective tissue disorder, referred to as Marfan syndrome type2 [11]. In 2005, Loeys et al. published their findings on a large series of patients presenting with widespread aggressive aortic disease with rapid growth and early dissections. They observed an increased prevalence of dysmorphic features including hypertelorism and cleft palate/bifid uvula. Patients harbored mutations in either the *TGFBR1* or *TGFBR2* gene and the disorder was

named after the authors (Loeys-Dietz syndrome, LDS) [12]. Patients with LDS may also present with arterial tortuosity/aneurysms/dissections outside the aorta necessitating extensive vascular imaging at regular time intervals. With the identification of mutations in genes involved in the *TGFβ* pathway, a new era with regards to our understanding of the pathophysiology and treatment of TAAD emerged. Other gene mutations have been identified including the *SMAD3* gene causing Aneurysm-Osteoarthritis syndrome and mutations in the *TGFβ* ligand. In view of the important clinical overlap between these disorders, the term “*TGFβ* associated vasculopathies” may be preferred over individual syndrome names.

The genetic background of nonsyndromic TAAD is even more complex and heterogeneous. Genes involved in syndromic forms may also be encountered in patients with isolated aortic disease, emphasizing the fact that the clinical spectrum of these disorders is very broad. Other genes involved in nonsyndromic TAAD include the *ACTA2* gene (encoding smooth muscle α -actin), the *MYLK* gene, encoding myosin light chain kinase and the *MYH 11* gene encoding the myosine heavy chain subunit [4,13–15]. The proteins encoded by these genes are involved in the vascular smooth muscle cell apparatus. Patients present with TAAD, sometimes in association with other features such as livedo reticularis, iris flocculi, and cardiovascular disease in the case of *ACTA2*, patent ductus arteriosus in the case of *MYH11*, and gastro-intestinal disease in the case of *MYLK*.

Establishing a correct diagnosis of TAAD in an individual patient primarily requires detailed clinical evaluation of the proband and family members (see below). It should be noted, however, that substantial clinical overlap exists between these subgroups. Therefore, additional molecular genetic testing may be helpful and sometimes even required for confirmation of the specific diagnosis.

Strategy for Clinical Evaluation and Genetic Testing

The absolute prerequisite for further clinical/genetic investigations in TAAD patients is a correct diagnosis of the aneurysm itself, based on careful measurement of the diameter of the aorta according to appropriate guidelines [35]. The measurements obtained need to be correlated to values in normal subjects matched for age, body surface area, and gender [36]. To correlate with normal values, nomograms

Table 1. Schematic Overview of Syndromic and Nonsyndromic TAA (Thoracic Aortic Aneurysm and Dissections)

Disorder	Gene(s)	Main Cardiovascular Features	Additional Clinical Features
Marfan (1, 16, 17)	<i>FBN1</i>	Syndromic TAA Aortic Root Aneurysm, Aortic Dissection, Mitral Valve Prolapse, Main Pulmonary Artery Dilatation, Left Ventricular Dysfunction	Lens luxation , skeletal features (arachnodactylia, pectus deformity, scoliosis, flat feet, increased armspan, dolichocephalia)
Ehlers-Danlos (18–20) (vascular, valvular)	<i>COL3A1</i> , <i>COL1A2</i>	Arterial Rupture and dissection without preceding dilatation/aneurysm, severe valvular insufficiency	Thin, translucent skin, dystrophic scars, facial characteristics (Madonna face, thin lips, deep set eyes)
TGFβ-related vasculopathies	Loeys-Dietz (2, 12) Aneurysm-Osteoarthritis (21–23) <i>TGFβ2</i> (24, 25)	<i>TGFBR1/2</i> <i>SMAD3</i> <i>TGFβ2</i> Mild aortic root dilatation, mitral valve prolapse	Bifid uvula/cleft palate, hypertelorism , pectus abnormalities, scoliosis, club feet Osteoarthritis , soft skin, flat feet, scoliosis, recurrent hernia's, hypertelorism, pectus abnormalities Club feet, soft translucent skin
Shprintzen-Goldberg syndrome (26, 27)	<i>SKI</i>		Craniosynostosis, distinctive craniofacial features , skeletal changes, neurologic disabilities
Arterial Tortuosity Syndrome (28) Cutis Laxa Syndromes (29)	<i>SLC2A10</i> <i>FBLN4</i>	Arterial Tortuosity, Arterial Stenoses and Aneurysms Aortic Root Aneurysm, Arterial Tortuosity	Hyperlax skin and -joints Hyperlax skin and -joints, mild emphysema
Familial thoracic aortic aneurysm syndrome (FTAA) (30–32)	<i>TGFBR1/2</i> (3–5%) <i>ACTA2</i> (10–14%)	Non Syndromic TAA Thoracic Aortic Aneurysm/Dissection Thoracic Aortic Aneurysm/Dissection, cerebrovascular disease, coronary artery disease	Lack of syndromal features Lack of Marfanoid skeletal features, livedo reticularis, iris flocculi, coronary artery/cerebrovascular disease) Gastro-intestinal abnormalities
FTAA with bicuspid aortic valve (BAV) (33, 34)	<i>MYLK</i> <i>SMAD3</i> (2%) <i>TGFβ2</i> <i>ACTA2</i>	Thoracic Aortic Aneurysm/Dissection Intracranial and other arterial aneurysms Mitral valve prolapse	Lack of Marfanoid skeletal features, livedo reticularis, iris flocculi
FTAA with patent ductus arteriosus (PDA) (6)	<i>NOTCH1</i> <i>MYH11</i>	Highly calcified Valve Patent ductus arteriosus	

Overview of syndromic and nonsyndromic forms of TAA with their corresponding genes and clinical features. Discriminative features are in bold.

can be used or z-scores can be calculated, the latter method being more convenient for reporting. Aortic dilatation is confirmed if the z-score exceeds 2, corresponding to an observed value >1.96 standard deviations above the predicted value for age, gender, and body size. In children, growth needs to be taken into account and z-scores >3 have been suggested [37]. Further investigations will depend on the age and cardiovascular risk profile of the patient.

Consideration of a genetic entity is especially of interest in young subjects with no additional risk factors. Detailed family history taking, including pedigree drawing and clinical assessment of first degree relatives, is required to differentiate between familial and isolated forms of TAA. Next, careful multidisciplinary clinical evaluation of the proband is undertaken, which will help us in the identification of specific syndromes as reported in Table 1.

Since TAA is a genetically heterogeneous disease with important clinical overlap between the known genetic entities, there is a clear need for simultaneous testing of multiple genes. Until recently, strategies for genetic testing were limited as only one gene at the time could be analyzed, and both the time required as well as the costs for screening of multiple genes were substantial. The need for high-throughput techniques enabling simultaneous testing of several genes was met by the recent development and progress made in the field of Next Generation Sequencing. Previously, our Center reported a mutation detection strategy using massive parallel sequencing of the *FBN1* and *TGFBR1* and *-2* genes for the molecular diagnosis of MFS and LDS [38]. In a next stage, we implemented a novel screening strategy that allows simultaneous sequencing of 16 TAA-associated genes. To this purpose, two complementary panels of genes were designed, of which all coding regions and flanking sequences can be amplified in a fully automated fashion followed by sequencing on an Illumina MiSeq sequencer (Illumina, San Diego, California). The first gene panel comprises *FBN1*, *TGFBR1/2*, *SMAD3*, *TGFB2*, *ACTA2*, and *COL3A1*. The second gene panel comprises *MYH11*, *MYLK*, *SLC2A10*, *NOTCH1*, *FBN2*, *ADAMTS10*, *FBLN4*, *FLNA*, and *ELN*.

Correct interpretation of the results obtained by molecular genetic testing requires basic knowledge of these different genes and clinical entities - all the more since medical and surgical management may differ according to the underlying diagnosis.

Importantly, the simultaneous sequencing of multiple TAA-associated genes is not always justified. In patients presenting with a thoracic aortic aneurysm in combination with lens luxation for instance, Marfan syndrome is very likely and molecular genetics can be restricted to the *FBN1* gene. Or, from a cardiovascular perspective, extensive vascular disease such as aortic aneurysms at different locations and/or involvement of side branches makes a diagnosis of Marfan syndrome much less likely and in these cases, TGF β -associated disease should be excluded first. A flow chart illustrating the diagnostic process (clinical and genetic evaluation) is provided in Figure 1.

Genes and Pathogenesis

In addition to its usefulness in a diagnostic setting, molecular genetics have been very useful in unraveling the complex pathogenesis of TAA formation. One of the most inspiring findings over recent years was the observation of the involvement of the Transforming Growth Factor β (TGF β) pathway in several connective tissue disorders. The TGF β superfamily consists of a number of cytokines that regulate diverse cellular functions, including proliferation, differentiation, and synthesis of a wide array of gene products.

The first heritable connective tissue disorder linked to the TGF β pathway was Marfan syndrome (MFS). The underlying pathogenesis of aneurysm formation in MFS was initially considered to be a consequence of inherent structural weakness of the tissues due to structurally abnormal fibrillin-1 fibers. Prospects for causal treatment were pessimistic in this view since this would require a means to alter the structural composition of inherently weak tissues.

Fortunately, recent developments have changed this insight and it is now recognized that fibrillin-1 containing microfibrils also play an important functional role in the complex TGF β pathway. Although it is clear that the TGF β pathway plays a role in the pathogenesis of MFS, the mechanism of TGF β activation remains controversial. On the one hand, it has been suggested that TGF β is activated as a consequence of improper sequestration of the latent TGF β complex, which is the result of a reduction of fibrillin-1 below a certain threshold [39]. On the other hand, Charbonneau and colleagues demonstrated that an *Fbn1* mouse in which the latent TGF β binding protein site (LTBPs) was deleted (*Fbn1*^{H1 Δ}) did not present

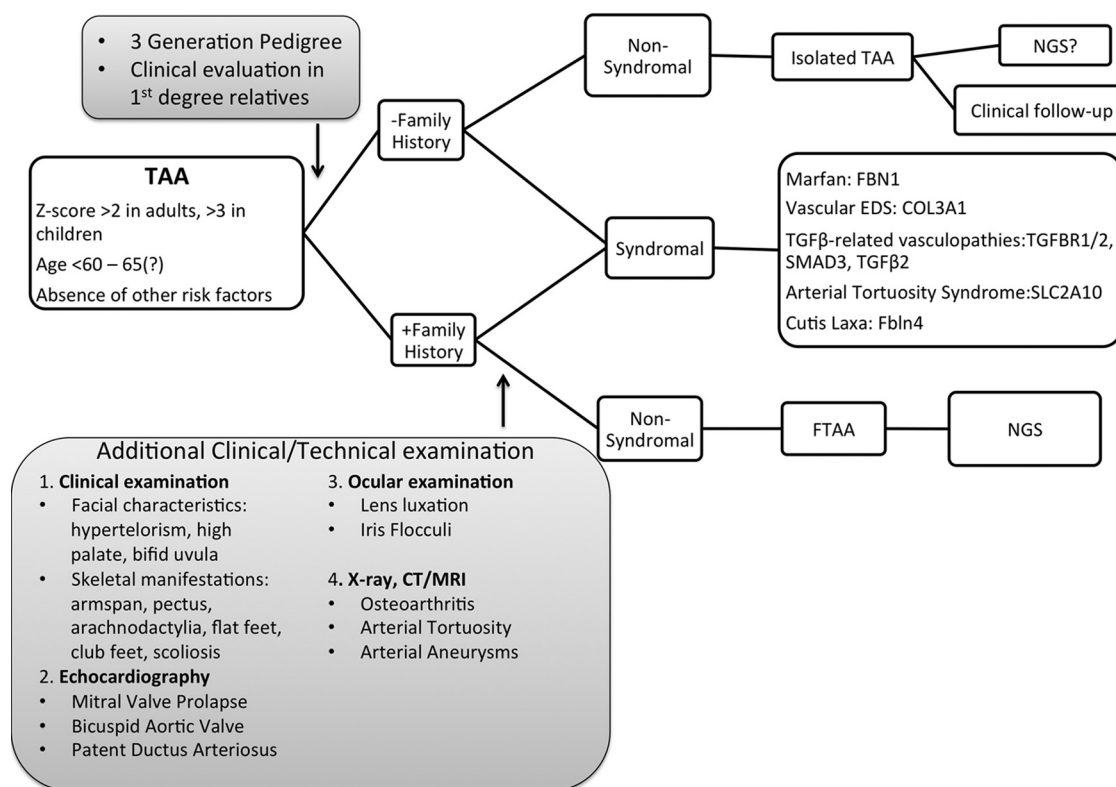

Figure 1. Flow chart illustrating the diagnostic process (clinical and genetic evaluation). NGS: Next Generation Sequencing.

features of MFS [40]. Hence, instead of reduced TGFβ sequestration, mutant microfibrils probably influence TGFβ activation in a different way. Sakai and coworkers demonstrated that fibrillin-1 was homologous to the family of LTBP which serve to hold TGFβ in an inactive complex in various tissues, including the extracellular matrix [41]. Fibrillin-1 binds TGFβ and LTBP [41–44].

Since the large latent complex binds TGFβ, abnormal fibrillin-1 fibers will lead to failed matrix sequestration of the latent TGFβ complex and hence to increased amounts of active TGFβ, which is in turn at the basis of the pleiotropic manifestations in MFS [39]. Indeed, increased TGFβ signaling has been demonstrated in aortic tissue samples and in mitral valve tissue from patients with MFS. These findings have opened new perspectives for treatment through inhibition of TGFβ-signaling (see below).

Additional evidence for the involvement of the TGFβ pathway in aneurismal disease came from the findings that mutations in several genes that encode different components of the pathway result in aneurysm conditions that have undeniable clinical overlap

with MFS. Initially, these disorders were given names, the first one being the Loeys-Dietz syndrome (LDS), caused by mutations in the TGFBR1 and TGFBR2 genes. In 2011, mutations in the SMAD3 gene were identified in patients with a very similar phenotype but also presenting with osteoarthritis, hence the name “Aneurysm-Osteoarthritis syndrome (AOS).” Soon thereafter a family with juvenile polyposis associated with aortopathy and mitral valve disease caused by SMAD4 mutations was reported [45]; and finally, mutations in the TGFβ-2 ligand were very recently identified in several families displaying a very similar phenotype [25,46,47]. It is clear that these disorders are all part of a broad spectrum and it may be more convenient to group them under the term “TGFβ-related vasculopathies.” Figure 2 provides a schematic and abbreviated overview of the TGFβ signalling pathway with indication of aneurismal diseases linked to it.

Increased TGFβ signaling has also been reported in human aortic specimens of patients with familial TAAD and underlying ACTA2 or MYH11 mutations [48]. The exact link is not yet fully understood but links

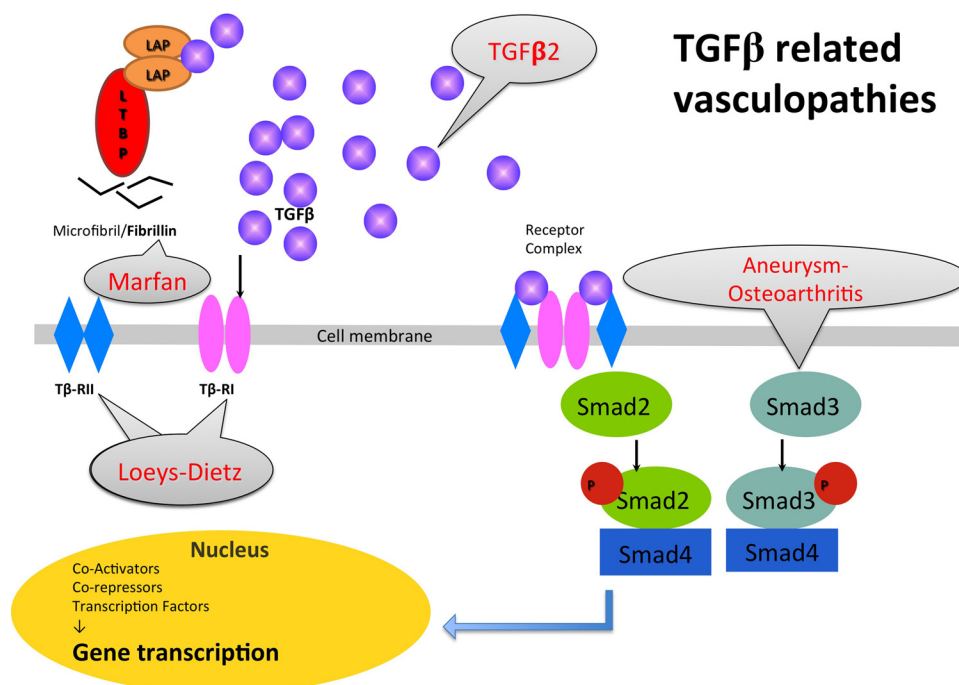

Figure 2. Provides a schematic and abbreviated overview of the TGFβ signaling pathway with indication of aneurismal diseases linked to it. The TGFβ pathway and related vasculopathies. Following its release from the Extracellular Matrix, TGFβ binds to its type II cell surface receptor (TβRII), which recruits and phosphorylates the type I receptor (TβRI). TβRI then recruits and phosphorylates SMAD2 and/or SMAD3. These P-SMADs then bind to the common SMAD (co-SMAD) SMAD4 to form a heterodimeric complex. This complex enters the cell nucleus where it acts as a transcription factor for various TGFβ-dependent genes, such as connective tissue growth factor (CTGF), plasminogen activator inhibitor-1 (PAI-1) and multiple collagens.

between the contractile cytoskeleton and many aspects of the TGFβ signaling pathway have been established, including trafficking and activity of TGFβ receptors and signaling effectors [49,50].

Gene-Tailored Follow-up and Management in TAAD

A schematic overview of the medical management is provided in Table 2.

Imaging Studies

Confirmation of the exact diagnosis in the proband facilitates the set-up of a personalized strategy for follow-up and treatment in the patient and his/her family. Since the clinical manifestation of the disease is age dependent and may progress subclinically until later in life, lifelong follow-up is required in all mutation-carriers, even if aortic diameters are normal on repeated measurements. The frequency and modality for follow-up and treatment may differ according to the underlying diagnosis as summarized in Table 2. Importantly, clinical monitoring and follow-up with

cardiovascular imaging is also warranted in family members of TAAD patients in whom no causal mutation was identified since familial clustering is observed in more than 20% of TAAD cases [51,52].

Echocardiography is the primary imaging tool for evaluation and follow-up of the diameters of the aortic root and ascending aorta. CT or MRI can be used in case of insufficient visualization of the ascending aorta by echocardiography. The imaging study should be repeated in all patients six months after the initial diagnosis to assess evolutionary changes. Further follow-up is guided by the diameter, evolution, underlying diagnosis, and family history. Stable diameters <45 mm in patients with Marfan syndrome or isolated TAA and no family history for dissection require yearly follow-up. Biannual controls are recommended in all other cases.

On initial diagnosis, imaging of the entire aorta and side branches ("head-to-pelvis" study) should be performed in order to detect aneurysms at other sites

Table 2. Overview of Suggested Treatment and Follow-up in TAA

Disorder	Treatment	Follow-up
Marfan (1, 16, 17)	<p>β-blocking agents, losartan?</p> <p>surgery when AoD >50 mm or >46 mm in case of familial history of dissection or rapid growth (>2 mm/y) or severe AR or MR</p> <p>Celiprolol</p> <p>Surgery uncertain</p> <p>No trials yet — adopt medical treatment from Marfan syndrome</p>	<p>echocardiography q1y when diameter <45 mm q6m in all other cases</p> <p>MRAq5y when aortic diameters outside the sinuses of Valsalva are normal, MRAq1y in all other cases</p> <p>Unclear (dissection/rupture often at normal diameters)</p> <p>Echocardiography q6mo</p>
Ehlers-Danlos (18-20) (vascular, valvular)		
TGF β -related vasculopathies	<p>Loeys-Dietz (2, 12)</p> <p>Aneurysm-Osteoarthritis (21–23)</p> <p>TGFβ2 (24, 25)</p>	
Arterial Tortuosity Syndrome (28)		
Cutis Laxa Syndromes (29)		
Familial thoracic aortic aneurysm syndrome (FTAA) (30–32)	<p>Surgery when AoD >43–45 mm</p> <p>No trials yet — adopt from Marfan syndrome</p>	<p>CT/MRI head to pelvis q6mo-1y</p> <p>Same as in Marfan syndrome</p> <p>Consider coronary/cerebrovascular imaging in ACTA2 mutation carriers</p> <p>Echocardiography q6mo-1y (also related to valvular function)</p> <p>Same as in Marfan syndrome</p>
FTAA with bicuspid aortic valve (33, 34)	<p>No trials yet — adopt from Marfan syndrome</p>	
FTAA with patent ductus arteriosus (6)	<p>No trials yet — adopt from Marfan syndrome</p>	

AoD: Aortic Root Diameter; AR: Aortic Regurgitation; MR: Mitral Regurgitation; MRA: Magnetic Resonance Angiography.

and/or arterial tortuosity. Regular extensive vascular imaging from head to pelvis is recommended in patients with a *TGFBR1/2*, *SMAD3*, and *TGFBR2* mutation and for rare diseases such as cutis laxa and arterial tortuosity syndrome (ATS). In vascular Ehlers-Danlos syndrome (EDS) where dissections often occur at normal diameters, the modality and frequency of vascular imaging is debatable. Evaluation for coronary artery and cerebrovascular disease can be considered in patients with an *ACTA2* mutation [53].

Medical Treatment

The initial medical approach of TAAD patients should include reduction of cardiovascular risk factors, such as blood pressure control, smoking cessation, and optimization of the lipid profile. Central stimulating drugs, such as cocaine, amphetamine and derivatives are known triggers for aortic dissection and should therefore be avoided [54,55].

Medical treatment with a β -blocking agent in MFS reduces the progression of aortic dilatation in most patients through reduction of wall shear stress in the aorta and is used as a standard therapy in MFS patients [56]. As already mentioned, it has been clearly demonstrated that the *TGFBR* pathway plays an important role in aneurysmal disease. This knowledge has led the search for strategies to interfere with *TGFBR* signalization. From studies in nephrology, it was documented that losartan, an angiotensin receptor blocking agent, inhibits *TGFBR* signaling. An initial experiment with *TGFBR* neutralizing antibodies in a mouse model for MFS showed a dramatic decrease in aortic root growth as well as restoration of aortic wall architecture [57]. A trial with losartan in MFS mice showed significant rescue of aortic root aneurysm progression as well as aortic wall architecture, compared to treatment with either placebo or propranolol [57]. A subsequent small study in children with severe MFS showed similar very promising results [58]. Large-scale trials in MFS patients are currently underway [59] and need to be awaited prior to large-scale prescription.

In patients with vascular EDS, reduction of fatal vascular events was observed with treatment with celiprolol, a β -blocker with β_2 mimetic action [60]. The possible role of medical treatment in other TAAD diseases is not well studied but pragmatically, treatment as for MFS is adopted.

Surgery

It is beyond any doubt that elective surgical aortic root replacement leads to better survival in patients with genetic aortic disease. Modalities for surgical intervention are beyond the scope of this contribution. We do want to spend some words on the timing of surgery taking the underlying diagnosis into account.

It has been demonstrated that the risk for dissection or rupture for thoracic aortic aneurysms of non-degenerative origin rises at lower diameters when compared to degenerative aortic disease. Accordingly, the threshold for surgery of the aortic root is lower than the conventional 55 mm. Indeed if conforming to the European Society of Cardiology guidelines on Grown-up Congenital Heart Disease, the conventional surgical indication for MFS is an aortic diameter-measured at the sinuses of Valsalva at 50mm or more. This threshold is reduced to 46 mm in the case of a positive family history of aortic dissection or rapid growth of the aorta (>2 mm/yr). When there is a desire of pregnancy, aortic repair at 45 mm is recommended [61]. In certain other syndromic and nonsyndromic TAAD entities such as LDS or AOS, aortic dissection can occur at smaller diameters, therefore requiring an adjusted treatment policy. Results of surgical intervention in LDS and AOS are good [3,62]. Taking these data into account, the current guidelines of the American College of Cardiology recommend prophylactic surgery in the following cases [63,64]: (i) patients with a mutation in *TGFBR1* or *TGFBR2* (as well as patients with LDS as familial TAAD), when the diameter of the ascending aorta reaches 42mm measured by echocardiography or 44–46 mm on CT or MR imaging; (ii) patients with familial TAAD and/or mutation in *MYH11* or *ACTA2*, when the diameter of the ascending aorta measures between 45 and 50 mm; (iii) patients with familial TAAD with relatives with an aortic dissection at minimal dilatation of the thoracic aorta (<50 mm); (iv) for all other TAAD patients when the ascending aorta or aortic root reaches a diameter of 50 mm, in case of rapid growth of the aorta (≥ 5 mm/y) and/or in the presence of severe aortic stenosis or regurgitation. Patients with a mutation in the *MYLK* gene can have an aortic dissection at small diameters of the aorta, as indicated by the study of Wang et al. [15]. Guidelines regarding the role of prophylactic surgery in this group of patients are lacking. In contrast to patients with a *TGFBR2* mutation, aortic dissection in patients with a *TGFBR1* mutation would

rather occur at larger diameters (>50 mm) [65]. In view of these data, early referral for surgery may be questioned.

Conclusion

In the current era of improved availability of high-throughput molecular genetic techniques, knowledge of the indications and limitations for these tests in daily clinical practice is increasingly important. In the case of TAAD, additional genetic testing may be helpful for confirmation of the correct diagnosis. Since follow-up and treatment of patients may be adapted according to the underlying condition, clinicians dealing with these patients should acquire

this knowledge. Close collaboration between cardiovascular surgeons, cardiologists, and clinical geneticists is strongly recommended in the care of these patients and families.

EDITOR'S COMMENTS

Dr. De Backer and colleagues, from the distinguished Ghent group, provide a clinically oriented primer on the current state of knowledge regarding the genetics of thoracic aortic aneurysm. They tell us just how to use genetic testing in the present era. As well, they provide useful management and clinical guidelines that take into account the emerging knowledge of aneurysm behavior in specific genetic syndromes. They usher us into the era of personal-

ized aortic management based on molecular genetics.

The Editors only point of difference concerns frequency of imaging. Since the aorta grows very slowly in the vast majority of thoracic aneurysm patients (about 1 mm per year), after the first yearly ECHO, CT, or MRI are done, we decrease frequency of imaging to every two to three years. (ECHOs can be done frequently, if desired, because of low cost and zero toxicity. We use restraint in CT and MRI.)
