Case Report

Anterior communicating artery aneurysm presenting with vision loss

ABSTRACT

Anterior communicating artery aneurysm rarely presents with symptoms of compression of anterior visual pathways. We report a case of 65 years old man, who had complete loss of vision in right eye and temporal hemianopsia in left eye due to giant anterior communicating artery aneurysm.

Key words: Aneurysm, anterior communicating artery, optic nerve, vision loss

Introduction

The aneurysms originating from carotid-ophthalmic artery, supraclinoid internal carotid artery, and internal carotid artery bifurcation are more likely to present with symptoms of anterior visual pathway compression.^[1] We describe a rare case of anterior communicating aneurysm presenting with vision loss.

Case Report

A 65 years old, gentleman presented with headache of 3 months duration, and loss of vision in right eye of 15 days duration. He was suffering from non specific headache for which he did not seek medical attention. About 15 days back his vision decreased in right eye, which progressed to complete blindness within a week. He never had sudden onset of headache with vision loss. At admission he was conscious and alert. His best corrected visual acuity was no perception of light in right eye and 6/6 in left eye. He had relative afferent pupillary defect in right eye, and brisk pupillary reaction to light in left eye. The fundoscopy revealed

pale disc in right eye and normal disc in left eye. The visual fields assessment was done with computerized static visual field analysis using zeiss humphrey. The SITA FAST test was performed using goldmann parameters. Right eye could not be assessed because of poor vision. The left eye showed temporal hemianopsia. He did not have any other neurological deficits. The blood investigations revealed normal hematological and biochemical profile. The visual evoked potential revealed absence of all waves in right eye, and increased latency (N75-77.1 ms, P100-113.1 ms, and n145-157.8 ms) in left eye. Unenhanced CT scan of head showed a hyperdense suprasellar lesion. The MRI of brain showed a well defined rounded suprasellar lesion measuring 26 × 25 × 23 mm, which was composed of concentric rings of differing intensities, suggestive of partially thrombosed giant aneurysm. Post contrast MRI showed an aneurysm arising from anterior communicating artery (AComA), which was directed posteriorly [Figure 1]. Digital subtraction angiography (DSA) confirmed the findings on MRI [Figure 2]. The patient was offered surgery for securing aneurysm. As there was uncertainty about visual recovery he did not opt for any treatment and was discharged against medical advice.

Discussion

Large or giant aneurysm arising from anterior part of circle of Willis can result in visual symptoms as it is in close proximity to anterior visual pathways. The visual loss due to aneurysms is characterized by

fluctuation, unlike that from tumors where visual loss is gradually progressive. These fluctuations are due to thrombosis or intermittent dilatation of aneurysm.^[1] The common origins of aneurysms that present with symptoms of anterior visual pathway compression are carotid-ophthalmic artery, supraclinoid internal carotid artery, and internal carotid artery bifurcation. Aneurysms arising from these arteries are often large or giant and can compress the visual apparatus. The AComA aneurysms rupture before becoming large enough to compress visual pathways, hence they present with subarachnoid hemorrhage rather than visual symptoms.^[1] Giant AComA aneurysms are extremely rare and may present with vision loss.^[2] Visual apparatus compression can occur from giant AComA aneurysm directed posteriorly and inferiorly as in our case.^[1,2] The pattern of visual loss in these cases is variable. The common pattern of visual loss is bilateral field deficits.^[1] Presentation with only monocular acute visual loss is very rare, and when it occurs, contralateral eye is more often affected.^[3] The other patterns of visual loss due to AComA aneurysms are central scotoma, bilateral heteronymous deficits, monocular or binocular inferior field loss, asymmetrical bitemporal hemianopsia, and incongruous homonymous hemianopsia.^[1] In our case, patient presented with subacute monocular visual loss. The opposite side temporal field defect was detected only on detailed visual field assessment, for which patient

was asymptomatic. The visual field deficit might have started with bitemporal hemianopsia due to chiasm compression, which would have not been noticed by the patient. The right optic nerve would have got compressed later, presenting with monocular visual loss. The common mechanism of visual loss is compression and ischemia due to giant aneurysm, as in our case, and direct hemorrhage in the optic nerve or chiasm due to rupture of smaller aneurysm.^[1] The penetration, splitting, or fenestration of optic nerves by aneurysms is extremely rare.^[4]

The predictability of recovery of vision is poor in case of aneurysmal visual loss. In a review of 165 cases of aneurysmal visual loss, visual function improved in 70% cases, remained unchanged in 21%, and worsened in 9% after surgical clipping. There was no significant relationship between visual recovery and aneurysm location, aneurysm size, or presence of subarachnoid hemorrhage. Surgical clipping was significantly associated with better visual outcome as compared to endovascular coiling.^[5] As the numbers of cases of visual loss due to AComA are rare the exact figure of visual outcome is not available.^[6] The results of treatment are variable ranging from no improvement to complete recovery.^[7] A patient with only a direct compression of the nerve by the aneurysm with no bleed can be expected to improve after surgery.^[3]
