Editorial

Hypoparathyroidism Should Always Be Checked in Papilledema

The term papilledema is most often understood as optic disc edema occurring as a consequence of intracranial hypertension. It has been proposed to use this term in this meaning only, excluding thus disc swelling from vascular causes, optic nerve neuropathies, or other reasons.^[1]

The clinical picture of papilledema can actually also occur in patients with hypocalcemia of any cause. In the pediatric population, DeGeorge syndrome is one of the possible causes.^[2] Such papilledema is almost always bilateral and usually causes minimal or no reduction in visual acuity, sometimes even no blind spot enlargement, at least not early. There have been several documented cases of later papillary atrophy, however. The blurring of vision can sometimes be the leading clinical sign even in the acute phase.^[3]

Most commonly, it has been reported with primary or secondary hypoparathyroidism. It occurs only when hypocalcemia is severe, and it improves with its reversal. The underlying pathophysiological mechanisms are not completely understood, but it seems likely that in severe hypocalcemia intracranial pressure can increase, probably due to cerebrospinal fluid (CSF) hypersecretion, less likely to decreased CSF absorption.^[4] Actually, papilledema in hypocalcemia probably represents one part in the spectrum of idiopathic intracranial hypertension. Some alternative theories have been proposed, including alterations in local tissue permeability, as there are case reports which show that the CSF pressures were normal. However, elevated CSF pressure has been documented in most cases.^[5]

Hypocalcemia is actually a rare cause of papilledema. However, it can be diagnosed very easily with serum calcium measurement, which should not be omitted. Even in the absence of other signs and symptoms of hypocalcemia, one should keep this possibility in mind. The authors of the instructive case report “Afebrile seizures as initial symptom of hypocalcemia secondary to hypoparathyroidism” have reminded us on this fact.^[6]

The diagnosis of hypocalcemia is more easily suspected with seizures. Both generalized and focal seizures can occur in hypocalcemia as the sole presenting symptom.^[6,7] The hallmark of hypocalcemia should be actually muscular irritability with tetany. However, some patients experience

rather less specific symptoms as fatigue or depression. Low CSF ionized calcium concentrations can have convulsive effects even in patients without any paresthesias, stiffness, myalgia, or cramps.
