ZUSAMMENFASSUNG

Methoden Diese Übersichtsarbeit basiert auf einer selektiven Literaturrecherche in PubMed, die den aktuellen Forschungsstand repräsentiert.

Kernaussagen:
- Die akute Ischämie der unteren Extremität ist ein interdisziplinärer Notfall. Er kann zum Extremitätenverlust führen und lebensbedrohliche Folgen haben.
- Sofortige Diagnosestellung und Therapieeinleitung sind entscheidend, um irreversible Schäden zu vermeiden.

ABSTRACT
Background Acute limb ischemia represents a clinical emergency with eventual limb loss and life-threatening consequences. It is characterized by a sudden decrease in limb perfusion. Acute ischemia is defined as a duration of symptoms for less than 14 days. Aging of the population increases the prevalence of acute limb ischemia. The two principal etiologies are arterial embolism and in situ thrombosis of an atherosclerotic artery. Immediate diagnosis, accurate assessment and urgent intervention when needed are crucial to save the limb and to prevent a major amputation. Delay in diagnosis and therapy may lead to irreversible ischemic damage.

Method To assess the current treatment options in acute limb ischemia, this review is based on a selective literature search in PubMed representing the current state of research.
Results and Conclusion Patients with acute limb ischemia should receive immediate anticoagulation. Treatment depends on the classification based on the degree of ischemia and limb viability. Especially acute (<14 days symptom duration) Rutherford Categories IIa and IIb with marginally and immediately threatened limbs require definitive therapeutic intervention and are salvageable, if promptly revascularized. The current literature suggests that open surgical revascularization is more time effective than catheter-directed thrombolysis. However, with the advent of thrombolytic delivery systems and mechanical thrombectomy devices, treatment time can be minimized and successful utilization in patients with Category IIb (Rutherford Classification for Acute Limb Ischemia) has been reported with promising limb-salvage and survival rates. Large randomized studies are still missing, and guidelines suggest choosing the method of revascularization depending on anatomic location, etiology, and local practice patterns, with the time to restore the blood flow being an important factor to consider.

Background

Acute limb ischemia (ALI) is a sudden, recent (less than 14 days duration) decrease in limb perfusion resulting in a threat to the viability of the lower extremity [1]. It is one of the most frequent causes for major amputation affecting approximately 1.5 persons per 10,000 per year [2]. Acute renal insufficiency, hyperkalemia and metabolic acidosis are possible systemic consequences of untreated ALI and are often life-threatening. Major amputation after ALI ranges between 10% and 15% while the associated 30-day mortality is documented as 15–25% [3]. The etiology of non-traumatic ALI can be categorized as embolic (30%), thrombotic (60%), or thrombosis of an existing stent or bypass graft. Cardiac emboli are the most common source of embolism (75%), with atrial fibrillation, recent myocardial infarction with mural thrombi, endocarditic vegetations and atrial myxoma as possible underlying causes. Aneurysmal diseased segments and proximal atherosclerotic debris are another source of emboli, when debris originating in proximal vessels dislodges and obstructs peripheral arteries. Less frequently, embolism is due to air, fat, amniotic fluid, or systemic tumor fragments or is iatrogenic. In rare cases paradoxical venous embolism in patients with a patent foramen ovale have been reported. Embolism recurs in 6–45%. Therefore, anticoagulation is important to prevent recurrence [4]. Anticoagulation leads to a reduction in the propagation of the thrombus and accumulation of free-floating thrombus formations. In general, indirect anticoagulants such as heparin, Vitamin K antagonists like phenprocoumon or warfarin need to be differentiated from direct anticoagulants like thrombin or factor Xa inhibitors. While direct oral anticoagulants (Non-Vitamin K Antagonist Oral Anticoagulant = NOACs) bind to and inhibit the activity of thrombin, indirect anticoagulants require a cofactor to interact with thrombin and therefore prevent blood clot formation. Heparin as an indirect inhibitor is administered sc. or iv., shows immediate effect, and is used in the initial management of ALI. On the other hand, thrombocyte aggregation inhibitors prevent platelets from clumping and are recommended in patients with underlying peripheral arterial disease, to reduce the risk of myocardial infarction, stroke, or chronic critical ischemia [5]. In addition, platelet inhibitors are used during and after peripheral arterial interventions, especially PTA with or without stent implantation.

In situ thrombosis occurs in a diseased local arterial segment with prior gradual atherosclerotic narrowing stimulating the formation of collateral channels. Rupture of an atherosclerotic plaque resulting in thrombus formation and arterial occlusion is discussed as the underlying pathomechanism [3].

Once the diagnosis is suspected, the severity of limb ischemia should be determined using the currently accepted classification system, introduced by the Society for Vascular Surgery (SVS) and adapted from the Rutherford classification (TASC II). In 1986, Rutherford first categorized acute and chronic limb ischemia based on clinical symptoms with objective (noninvasive) findings, emphasizing that the timing of symptom onset and different treatment algorithms are required. Unlike acute limb ischemia (ALI), critical limb ischemia (CLI) is defined by chronic ischemic rest pain, nocturnal recumbent pain, ischemic skin lesions, and symptom duration for at least 2 weeks [6]. To ensure clarity in communication and influence the urgency of revascularization, further therapeutic intervention is based on this clinical classification [7, 8] (Table 1).

Patients presenting with ALI have become progressively older. They suffer from multiple medical comorbidities that elevate the perioperative risk of surgical interventions. Therefore, endovascular strategies appear to be beneficial, especially in those patients.

Retrospective studies have investigated the efficacy and safety of endovascular therapies for ALI, with some suggesting improved limb salvage and mortality [9, 10]. In the most recent analysis, endovascular approaches aside from catheter-directed thrombolysis...
Complementary imaging

Since ALI is a clinical diagnosis, further investigations are carried out to confirm etiology and level/location of occlusion and to plan the therapeutic approach (e.g., access side). Based on fast availability, noninvasive imaging methods can be considered equal in patients categorized as IIb according to the Rutherford classification for acute limb ischemia allowing for better therapy planning [12].

Conventional arteriography (digital subtraction angiography-DSA), the former gold standard, is progressively being replaced by less invasive modalities [13]. It offers interventional therapeutic options for ALI but carries the risk of procedure-related complications (such as access bleeding), ionizing radiation and exposure to iodinated contrast medium. When renal function is normal, there seems to be no risk of contrast-induced acute kidney injury [14]. However, in patients with known impaired renal function, the risk for contrast-induced acute kidney injury may increase with eGFR < 30 mL/min/1.73 m² (ESUR Guidelines 10.0).

MR angiography has undergone significant advances in the past years providing good quality images with high sensitivity and specificity, compared to DSA. With the advent of numerous technical innovations, decreased total examination time coupled with a simultaneously clearer depiction of small vessels can be achieved [15]. Limitations are the need for more time-consuming sequences to get a better resolution of smaller arteries and reported overestimation of stenosis in native arteries and secondary to artifacts in case of vascular stents [16]. The risk of acute kidney injury is very low when gadolinium-based contrast agents are used in approved doses (ESUR Guidelines 10.0). Compared to conventional or CT angiography, it is rather time-consuming and often not feasible or available in the emergency setting.

CT angiography is noninvasive, readily available, cost-effective and can be used in patients with prior stents, pacemaker, or defibrillators (unlike MRA). It has proven to have comparable accuracy to MRA and has excellent spatial resolution. Advantages compared to conventional arteriography include multiplanar visualization and reconstruction, which can be useful for the evaluation of stenosis and identification of collateral vessels. In heavily calcified vessels, the ability to depict the lumen is limited despite editing algorithms, and dual-energy CTA is still said to overestimate high-grade vessels stenosis [17].

Duplex ultrasound enables identification and location determination and establishes the patency of outflow vessels. The main limitations are the inability to get a complete radiological road map, the fact that the method is operator-dependent, and technical limitations with respect to assessing the iliac arteries. The sensitivity for ultrasound decreases when the occlusion is located at or below calf level and in the case of heavy calcifications, and poor overall accuracy is known if multilevel disease is present [13].

To sum up, the preferred noninvasive imaging modality is commonly CT angiography, as it may promptly identify the level of the occlusion as well as the inflow and outflow situation, may demonstrate prior surgical or endovascular intervention, and may be obtained quickly. Nevertheless, the choice of diagnostic approach depends on the general patient condition and personal and technical conditions of each department.

Management of ALI

The first step in initial ALI management is immediate anticoagulation with heparin [8]. It was first introduced in 1978 by Blaisdell et al. [18] to prevent proximal and distal propagation of the thrombus. Heparin has no effect on the lysing of the established thrombus. It prevents thrombus formation and thereby avoids secondary thrombosis proximal and distal to the lesion and preserves the microcirculation. Patients should receive appropriate analgesia and proper handling of the limb and hydration, which may attenuate the contrast load they will receive and the potential myoglobinuria from reperfusion.

A treatment selection factor that is decisive for the treatment of ALI is the Rutherford classification based on the degree of ischemia and limb viability. Other factors guiding further clinical management are the duration of symptoms, surgical risk factors,
contraindications for thrombolysis, anatomical location, etiology and overall patient condition [8].

Category I ALI patients presenting with a viable limb may benefit from noninvasive diagnostic imaging and noninvasive vascular and laboratory studies to ascertain possible underlying chronic vascular disease. The need for elective vascular intervention can be determined while optimizing risk factors [8, 19].

Category II ALI patients require urgent or emergent revascularization to prevent progression to category III. The duration of symptoms, contraindications, etiology and location of the occlusion are decisive for therapeutic options in category IIa ALI. Endovascular therapy proved to be superior to surgery to treat acute category IIa events when the duration of symptoms is less than 14 days [20, 21]. Patients who present contraindications or have an incomplete response to thrombolysis or symptoms lasting longer than 14 days may benefit from surgical revascularization. In general, embolic disease should be considered if the occlusion lies at a vessel bifurcation or trifurcation [12].

Category IIb ALI indicates a profoundly ischemic limb, and immediate revascularization is indicated [1]. Due to the associated time for reestablishing vascularization with catheter-directed thrombolysis (CDT), traditionally open surgical revascularization has been performed. However, with the advent of mechanical thrombectomy devices, the treatment time can be minimized and successful utilization in patients with category IIb ALI is reported with increasing frequency [8]. More recent case series reported similar revascularization rates with endovascular treatment with decreased 30-day morbidity and mortality compared to open surgery [12, 19].

Large multicenter trial data for this group of patients are still missing and the guidelines suggest choosing the method of revascularization depending on the anatomic location of the occlusion, etiology of ALI, contraindications to open or endovascular treatment and local practice patterns [1, 22].

Category III ALI patients present major tissue loss along with permanent nerve damage. Revascularization is not indicated and can actually lead to reperfusion-related organ dysfunction and death. After initial stabilization, amputation should be considered.

In general, patients with category I ALI need urgent revascularization (e.g. within 12 hours of presentation), while patients with category II ALI need emergent revascularization (e.g. within 2–6 hours of presentation) [12].

Patients presenting with an acute graft occlusion usually suffer from progression of their atherosclerosis as the underlying causative reason. The guidelines suggest thrombolysis with subsequent PTA/stenting or surgical revision [1]. Local lysis is associated with bleeding complications and intensive patient monitoring. Surgical thrombectomy on the other hand shows perioperative complications and only small technical success rates in randomized trials [3, 23, 24]. Percutaneous mechanical thrombectomy (PMT) has also been proven to be an effective and safe therapy option in addition to the established lysis therapy [25].

Endovascular treatment technique

Four consecutive steps are necessary for an endovascular approach: Diagnostic angiography, lesion crossing, management of the thrombus, and an approach with special regard to a potentially underlying lesion. Reperfusion of the affected limb can be achieved by use of a thrombolytic agent alone or in conjunction with a mechanical device for aspiration, fragmentation of the thrombus, angioplasty, and optional stenting. Bleeding, vascular injury, and distal embolization are some of the associated complications [19]. There is a lack of prospective data. However, the use of adjunctive mechanical therapies has increased over time, supported by observational analysis [26].

The choice will depend on the presence of a neurological deficit, duration of symptoms, affected artery, patients’ comorbidities and risk factors, whether it is a native artery, therapy-related risks and outcomes. In more severe cases with neurological deficit, extraction and aspiration of the thrombus or surgical therapy are preferable. In patients with threatened limbs, the time to re-establish perfusion by thrombolysis is usually regarded as too long and the development of compartment syndrome is reported in up to 10% of cases [27]. In the absence of neurological deficit, catheter-directed thrombolytic therapy is more appropriate [28].

Catheter-Directed Thrombolysis (CDT)

The CDT approach is recommended in Category-IIa ALI with a short duration of symptomatology (<14 days) where the thrombus is still fresh and there is adequate time for the thrombolytic agent to perform its intended function. In the literature, information about dosing and duration of thrombolytic therapy differs extensively and can range between 2.5 and 48 hours in the exemplary case of alteplase [12, 29]. The following protocols are recommended: 1. weight-adapted administration of alteplase with 0.001–0.02 mg/kg/h or 2. Non-weight-based administration of alteplase with 0.12–2.0 mg/h (maximum dose: 40 mg). In both scenarios additional low-dose intraarterial heparin (400–600 IU/h) to avoid new thrombus formation should be discussed [20]. A more recent study found that the addition of continuous heparin infusion during intra-arterial thrombolysis had no significant benefit and was associated with a few major bleeding complications (30.3%) [30]. Although most of the reported bleeding episodes were mild and could be managed without surgical intervention, especially in elderly multimorbid patients, the associated risks must be weighed individually. For reteplase subsequent protocols are recommended: From 0.25 to 1.0 mg/h (maximum dose: 20 IU in 24 h) or in a low-dose regimen: 0.125 mg/h. Tenecteplase should be administered as a bolus infusion of 1–5 mg, followed by infusions ranging from 0.125–0.5 mg/h [20].

An increased risk of hemorrhagic complications is said to occur in low-dose, long-duration thrombolytic infusions. On the other hand, an elevated risk of distal embolization may be associated with high-dose, short-duration thrombolytic infusions. The infusion of the thrombolytic agent may be continuous, pulse-spray, or initial pulse-spray with subsequent continuous infusion, the idea behind the latter being to more rapidly penetrate and induce
fluctuation of the thrombus [12, 29]. To date, there is no standardization of the therapeutic protocol in regard to dosing and duration of the thrombolytic agent or monitoring of the patient. When comparing standard thrombolysis with ultrasound-accelerated thrombolysis (UST), a multicenter Dutch trial showed a significantly reduced therapy time with UST, but with a substantial number of bleeding complications [31]. Large cohort studies or systematic meta-analyses to show clinical benefits are missing [31–33].

There are different generations of thrombolytic agents, with each generation achieving increased specificity for fibrin-bound plasminogen. First-generation thrombolitics (streptokinase, urokinase) are no longer used due to the increased risk of hemorrhagic complications; second-generation agents (alteplase) act practically solely on fibrin-bound plasminogen; third-generation agents have less affinity for free circulating plasminogen (reteplase) or better resistance to endogenous inactivating factors in the plasma (tenecteplase) [12, 29]. Alfimeprase, a novel recombinant variant of fibrolase (direct fibrinolytic enzyme with no effect on plasminogen), first showed promising results in preclinical and pilot studies with regard to duration of therapy and risk of bleeding. In a multicenter study with two blinded, placebo-controlled, randomized trials, alfimeprase did not show life-threatening bleeding complications, but did not have greater effectiveness than placebo either [34].

Currently, in most cases, CDT is combined with target lesion endovascular/surgical correction to improve long-term patency rates and to decrease the amputation rate [35].

Historically, three multicenter randomized trials investigated the role of CDT against open surgery in ALI: the Rochester, STILE and TOPAS studies. Despite limitations in the heterogeneity of study populations and endpoints, no significant difference in limb salvage or death at 30 days, six months or one year between initial surgery and initial thrombolysis was found [34, 36–39]. The STILE study was the first study to demonstrate a significant outcome based on the duration of ischemia showing that in patients with ischemia <14 days the amputation rate for surgery was significantly higher (30%) compared to thrombolysis with rTPA or urokinase (UK) (11%). The trial was prematurely terminated due to the significantly higher incidence of re-thrombosis in the thrombolytic group. A major criticism of the STILE study was that the analysis concerning duration of ischemia (less or more than 14 days) was a post-hoc arbitrary division. However, in the thrombolysis group a higher incidence of stroke, major hemorrhage and distal embolization at 30 days were reported, without any overall difference in limb salvage or death at one year. In a Cochrane review, no evidence could be found either in favor of initial thrombolysis or initial surgery [39]. CDT can be used in combination or as an adjunct to other treatment approaches, after percutaneous thrombus aspiration, mechanical thrombectomy or PTA [40]. Some studies found significantly better patency in patients treated with CDT and angioplasty than in those treated with CDT alone [41].

Percutaneous thrombus aspiration (PAT) via large lumen catheters (6- to 8-French) was the first method of endovascular arterial thrombus extraction, which gained acceptance as a cheap method offering quick recanalization, especially in below-the-knee arteries [29]. Typically, it is utilized as a sole or an adjunct procedure in patients with thromboembolic complications after endovascular procedures [40]. It is a simple concept, with a stable end-hole catheter being delivered over the guidewire to the site of thrombus burden and a syringe placed at negative pressure being used to induce suction and to aspirate blood and thrombus fragments. It is crucial to use an introducer sheath with a removable hemostatic valve in order to fully retrieve the thrombus burden and to decrease the risk of thromboembolism during the process of thrombus extraction. Moreatraumatic and flexible catheters, encouraged from stroke approach, allow thrombectomy even from smaller arteries. Surprisingly, the number of studies analyzing the use of aspiration thrombectomy catheters in the peripheral vasculature is low. However, in many interventional institutions, this technique represents the treatment of choice in acute limb ischemia. In a retrospective study Kwok et al. [42] compared thrombolysis with primary aspiration embolectomy. Technical success was achieved approximately in half of the cohort by primary aspiration alone. PAT, if successful as a stand-alone treatment, obviates the requirement for CDT with a concomitant reduction in the risk of hemorrhagic complications [42]. Factors limiting widespread use are decreased effectiveness in cases of organized thrombus and in large vessels, less favorable results in patients with disseminated atherosclerotic lesions and the risk of inadvertent vessel injury if multiple catheter passages are required unless a long sheath with a removable hemostatic valve is placed close to the occlusion [29].

Mechanical thrombectomy devices can be classified according to the main mechanism of action: mechanical fragmentation, aspiration, rheolytic thrombectomy and combinations thereof. A recent trend is to combine mechanical thrombus removal with thrombolysis. The treatment time decreases compared to thrombolysis alone, and the thrombolytic agent dose can be reduced with a possibly lower bleeding risk. Due to technical limitations, endovascular thrombectomy is not always complete and the treatment of small-diameter vessels is frequently not feasible so that thrombolysis seems to be a reasonable adjunct in such cases [43].

The Rotarex® Device is based on a spiral, connected to the tip of the catheter, rotating at a speed of approximately 40,000 revolutions per minute to induce fragmentation of the thrombus. The rapid rotation of the helix generates a permanent vacuum inside the catheter which aspirates the thrombotic material and conveys it to a receptacle. Beneficial primary revascularization rates, especially with respect to elderly patients with multiple medical comorbidities, ranging from 70% to 96% have been reported previously [22, 44, 45]. By simultaneously performing aspiration during mechanical fragmentation of the clot, complications such as distal embolization are lower compared to CDT alone [22, 44]. The rapid debulking of the thromboembolism allows partial reperfusion to begin immediately in a controlled selective angiography setting, minimizes ongoing ischemia, and possibly unmasks underlying causative lesions. Concomitant PTA and stenting for the treatment of underlying flow-limiting lesions and stenosis greater than 50% can possibly lead to a significant improvement of the long-term patency and limb salvage rates. Unfortunately, rotational PMT was not approved for treatment in lesions distal
to the POP-II segment, and data are missing on rotational PMT in the iliac arteries. Recently, Kronlage et al. [46] compared mechanical thrombectomy to thrombolysis in a retrospective study and found that mechanical thrombectomy was not inferior to local thrombolysis, and that it was associated with a lower complication rate, shorter duration of hospitalization, and lower costs in a 12-moth follow-up.

The Angiojet® Device is based on a hydrodynamic aspiration mechanism. High-speed saline jets are injected through the catheter tip to create a so-called “venturi effect”. This results in a low-pressure zone with vacuum effect to simultaneously lyse and aspirate the thrombus [19]. The minimum diameter of treated vessels is 1.5 mm, a fact that allows effective treatment to the level of the crural arteries. The recommended maximum working time is limited to 300 s while working in the blood stream and 600 s within the thrombus due to hemolysis which occurs during the procedure [29]. There are prospective and retrospective studies analyzing rheolytic thrombectomy with and without pharmacologic thrombolysis, with an efficacy up to 90 % for recanalization [47, 48]. Potential complications are vessel injury and acute closure, distal embolization and stent graft collapse during thrombectomy, such as acute renal insufficiency and acute pancreatitis due to hemolysis [29].

Isolated Pharmaco-Mechanical Thrombolysis-Thrombectomy System (IPMT) by Trellis device aims to isolate the thrombus between two balloons followed by site-specific thrombolysis. The lysed thrombus is then aspirated while the inflated distal balloon prevents distal embolization. The total procedure time, systemic thrombolytic exposure and therefore bleeding complications are reduced when compared to CDT. Unfortunately, there are no relevant clinical data [49].

Ultrasound-based devices utilize high-frequency low-power ultrasound to enable the delivery of therapeutic agents in the peripheral vasculature. They consist of a reusable control system that powers the unit and a single-use infusion catheter system. The latter includes a drug delivery catheter (DDC) containing an ultrasound core (USC). It separates clot fibrin for better drug delivery into the clot without fragmentation of emboli and the principle of acoustic streaming hastens the penetration of the lytic agent into the clot. Ultrasound-based devices may provide a safe, effective, and time-saving treatment option. A few studies with small population sizes confirm high technical success rates of up to 100 %. However, clinical experience is limited and randomized studies are still missing [50]. These studies presume more rapid recanalization and a higher rate of early complete thrombus resolution by ultrasound-based devices compared to conventional lysis, thus reducing the hospitalization time [51].

Surgical Revascularization

Surgical revascularization is the treatment of choice in category IIa or IIb ALI with symptoms > 14 days, in the case of contraindications to thrombolysis or an endovascular approach, or in supragnostic occlusion [1, 8, 40].

Fogarty balloon catheter embolectomy was developed by Fogarty in 1963 [52]. After the advent of this technique, embolectomy and thrombectomy became easy and secure by approaching from the femoral artery. The procedure involves surgical exposure of the artery, usually at the common femoral or popliteal arteries. A horizontal arteriotomy is usually performed in embolic ALI, stenosis in subsequent closure can thus be minimized. In suspected thrombotic ALI on the other hand, a vertical arteriotomy is preferred. In that case, if subsequent bypass is needed, the same arteriotomy can be used for graft anastomosis. If no bypass is required, the arteriotomy should be closed using a vein patch to minimize potential stenosis [8]. Factors related to a successful outcome of the treatment of arterial embolism are an intact arterial intima, non-adherence of the thromboembolism to the intima, and a patent run-off vessel prior to embolization [4]. The catheter is introduced and pushed proximally beyond the thrombus and extracted after inflation of the balloon. This process is performed several times until all visible clots are removed and back bleeding is achieved [8]. After finishing the procedure, a completion angiogram in the operating room is recommended to exclude residual embolus and distal embolization and to secure patency of distal arteries, which allows immediate re-intervention [20].

Bypass procedures can be necessary in patients with ALI caused by thrombosis of underlying atherosclerotic disease. Patients with atherosclerotic native arteries tend to suffer from re-thrombosis, if balloon embolectomy is performed.

As mentioned above similar outcomes have been reported when comparing open surgical treatment with CDT with respect to amputation-free survival and overall mortality [34, 36–38].

While higher bleeding complications have been reported in thrombolysis, surgery showed increased morbidity related to cardiopulmonary complications, blood loss, wound infections and fasciotomy [53].

Conclusion

Acute limb ischemia is an interdisciplinary emergency, with variable presentation that may be life-threatening and lead to limb loss. Immediate diagnosis and treatment are critical to prevent irreversible damage. An endovascular approach should be considered in ALI categories IIa and IIb < 14 days, on a case-based decision, with special regard to elderly multimorbid patients with a high perioperative risk. In this setting, the structural, personal and technical conditions of each department must be considered.
