ABSTRACT

Introduction Optimal cytoreduction is the most important prognostic factor in advanced ovarian cancer. Although staging and assessment of operability are made by exploratory surgery, preoperative computed tomography (CT) of the abdomen is regarded as standard. The aim of this study was to

examine various CT parameters with regard to prediction of optimal cytoreduction.

Patients and Methods The retrospective study included 131 patients with ovarian cancer newly diagnosed between 2010 and 2014. Of these, n = 36 with FIGO stage I to IIB were excluded from the study. A preoperative abdominal CT was available for n = 75 of the 95 patients with FIGO stage IIC to IV. The CT scans underwent blinded review. The 11 evaluated CT parameters were examined by means of χ^2 test and logistic regression analysis with regard to the endpoints of macroscopic residual tumour and residual tumour > 1 cm. Survival analyses used the Kaplan-Meier method and log rank test.

Results Of 75 patients, 28 (37.3%) had complete tumour resection and 26 (34.7%) had residual tumour \leq 1 cm. Residual tumours > 1 cm were found in 21 (28%) patients, five of which were not resectable. Overall survival with residual tumour > 1 cm differed significantly from the group with no macroscopic residual tumour ($p = 0.003$) and with residual tumour \leq 1 cm ($p = 0.04$). The CT parameters tumour foci in the diaphragm, mesocolon, greater omentum and peritoneum as well as ascites correlated with macroscopic residual tumour. In the multivariate logistic regression analysis only the CT parameter intraparenchymal liver metastasis was statistically significant with regard to prediction of suboptimal tumour resection (> 1 cm) (OR 8.04; 95% CI 1.57–42.4; $p = 0.0134$). The sensitivity, specificity, PPV and NPV were 37.5, 89.7, 66.7 and 72.2%.

Conclusion Although risk parameters for suboptimal tumour reduction can be identified by CT of the abdomen, surgical exploration with histological confirmation of the diagnosis is essential because of the poor diagnostic accuracy.

ZUSAMMENFASSUNG

Einleitung Eine optimale Zytoreduktion ist der wichtigste Prognosefaktor beim fortgeschrittenen Ovarialkarzinom. Obwohl Stadieneinteilung und Einschätzung der Operabilität durch Explorativ-Operation erfolgen, gilt die präoperative Computertomografie (CT) des Abdomens als Standard. Ziel

dieser Studie ist die Überprüfung verschiedener CT-Parameter hinsichtlich der Prädiktion einer optimalen Zytoreduktion.

Patienten und Methoden In die retrospektive Studie wurden 131 Patientinnen mit zwischen 2010 bis 2014 neu diagnostiziertem Ovarialkarzinom aufgenommen. Davon wurden $n = 36$ im FIGO-Stadium I bis IIB aus der Studie ausgeschlossen. Von den 95 Patientinnen mit FIGO-Stadium IIC bis IV lagen bei $n = 75$ präoperative CT-Abdomen vor. Die CT-Scans wurden einem verblindeten Review unterzogen. Die evaluierten 11 CT-Parameter wurden mittels χ^2 -Test und logistischer Regressionsanalyse hinsichtlich der Endpunkte makroskopischer Tumorrest sowie Tumorrest > 1 cm überprüft. Überlebensanalysen erfolgten mittels Kaplan-Meier-Methode und Log-Rank-Test.

Ergebnisse Von 75 Patientinnen hatten 28 (37,3%) eine vollständige Tumorresektion und 26 (34,7%) Tumorreste ≤ 1 cm. Tumorreste > 1 cm fanden sich bei 21 Patientinnen (28%), da-

von waren 5 nicht resektabel. Das Gesamtüberleben bei Tumorrest > 1 cm unterschied sich signifikant von der Gruppe mit makroskopischer Tumorfreiheit ($p = 0,003$) bzw. Tumorrest ≤ 1 cm ($p = 0,04$). Die CT-Parameter Tumorherde am Diaphragma, Mesokolon, Omentum majus, Peritoneum sowie Aszites korrelierten mit makroskopischem Tumorrest. In der multivariaten logistischen Regressionsanalyse war lediglich hinsichtlich der Prädiktion einer suboptimalen Tumorresektion (> 1 cm) der CT-Parameter intraparenchymatöse Lebermetastase statistisch signifikant (OR 8,04; 95%-KI 1,57–42,4; $p = 0,0134$). Sensitivität, Spezifität, PPV und NPV betragen 37,5, 89,7, 66,7 und 72,2%.

Schlussfolgerung Obwohl mittels CT Abdomen Risikoparameter für suboptimale Tumorreduktion identifizierbar sind, ist wegen der geringen diagnostischen Genauigkeit die chirurgische Exploration mit histologischer Diagnosesicherung unverzichtbar.

Introduction

In 2016, ovarian cancer (OC) was responsible for one third of gynaecological cancers in Germany, with 7350 new cases, and for half of gynaecological cancer deaths, with approximately 5500 deaths. The prognosis is relatively poor because of late diagnosis (76% in stage III and IV). The relative 5-year survival rate is currently 43% [1]. Besides tumour stage, complete surgical tumour resection is considered to be the most important prognostic parameter for disease-free and overall survival. According to du Bois (2009), the effect was much more pronounced when there was no macroscopic tumour than after so-called optimal tumour reduction when residual tumours up to 10 mm remain in situ [2]. If no optimal cytoreduction is possible, the benefit of neoadjuvant chemotherapy followed by interval surgery was investigated in various studies [3–7]. Neoadjuvant chemotherapy does not appear to confer any benefit with regard to overall survival, so primary debulking surgery followed by six cycles of platinum-containing chemotherapy is regarded as standard [8]. Recent data from the prospective randomised Desktop III study on secondary cytoreduction for recurrent OC show that patients in whom complete tumour resection was possible in a secondary operation also have median overall survival that is more than 12 months longer [9].

Computed tomography (CT) of the abdomen as part of preoperative staging enables assessment of para-aortic lymph nodes, detection of liver metastases and of pleural effusions [10, 11]. As regards assessment of optimal cytoreduction, however, the data are controversial. While predominantly retrospective studies provide evidence that CT has high diagnostic reliability with regard to predicting optimal or suboptimal tumour reduction [12–16], two multicentre studies do not confirm these data [17, 18]. All studies refer to residual tumour ≤ 1 cm as the definition of optimal tumour reduction. The primary aim of this study was therefore to evaluate preoperative CT with regard to the endpoint no macroscopic tumour vs. macroscopic residual tumour. The secondary study aims were analysis of the CT parameters with regard to suboptimal tumour reduction (residual tumour > 1 cm), the influence

of residual tumour on overall survival and prediction of para-aortic lymph node metastases by means of CT.

Patients and Methods

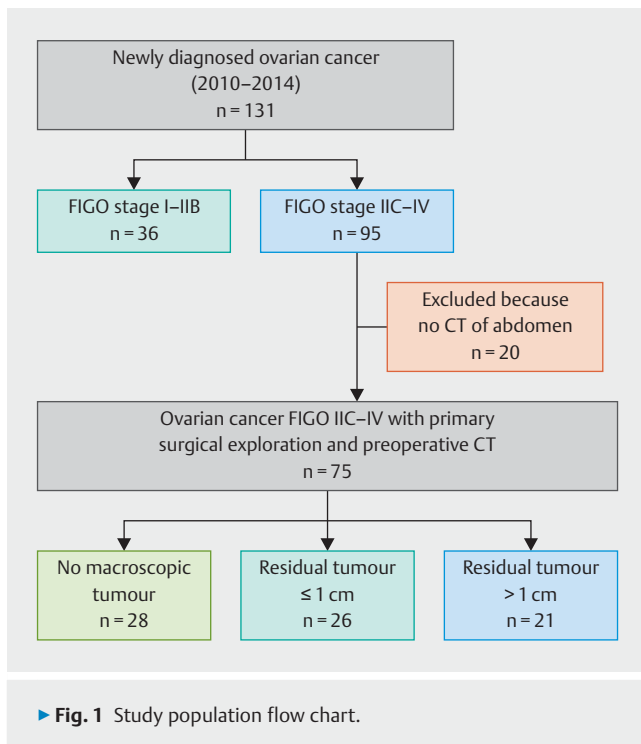

The retrospective study included all patients with a primary diagnosis of advanced OC at Rostock University Women's Clinic from 2010 to 2014. Patients with primary peritoneal cancer and tubal cancer were also included. Patients with non-epithelial ovarian tumours and tumours of borderline malignancy were excluded. Clinical data and histopathological features were obtained from the patients' files and the Mecklenburg-Western Pomerania clinical cancer registry.

Evaluation of the CT scans

The CT scans, stored in DICOM format, were reviewed by a radiologist experienced in oncology who did not know the surgical outcome. Based on the study by Axtell et al. (2007) the following CT parameters were recorded: metastases in the diaphragm > 2 cm, metastases in the mesocolon > 2 cm, involvement of the greater omentum, suprarenal lymph nodes > 1 cm, infrarenal lymph nodes > 2 cm, diffuse peritoneal thickening, pleural effusion, presence of ascites, peritoneal metastases > 2 cm, intraparenchymal liver metastases and involvement of the inguinal canal [18].

Surgical procedure

All patients had surgical exploration by one of two gynaecologists who subspecialise in gynaecological oncology with the aim of maximal cytoreduction. In accordance with the guidelines valid prior to publication of the LION (Lymphadenectomy In Ovarian Neoplasms) study [19], systematic pelvic and para-aortic lymph node excision (LNE) was performed in patients when R0 resection was pursued, and enlarged lymph nodes were removed otherwise. No patient had neoadjuvant chemotherapy. The surgeon's assessment regarding the operation outcome acted as diagnostic reference. Four categories were recorded initially: no macroscopic tumour, 1–10 mm tumour resection, tumour debulking with re-

residual tumour > 1 cm, non-resectable. For the statistical analysis, these were combined into the following groups: no macroscopic tumour vs. macroscopic residual tumour and residual tumour ≤ 1 cm vs. > 1 cm.

Statistical analysis

Statistical analysis was performed with SPSS Statistics 25 (IBM Deutschland GmbH, Ehningen). Survival analyses were carried out using the Kaplan-Meier method and log rank test.

For group comparisons we used the χ^2 test for categorical variables and Fisher's exact test when the case number was small. Quantitative characteristics such as age, body mass index (BMI) and Karnofsky index were combined into categories according to clinical relevance. The tumour marker CA 12-5 and serum albumin were not included because of a large number of missing values, and information about the BRCA status was also omitted as this was available only in isolated cases in the cohort. All variables with $p < 0.2$ in univariate analysis were included in the multivariate analysis. Binary logistic regression of independent variables, which generates the adjusted odds ratio (aOR) and corresponding p-values and 95% confidence intervals (95% CI) served as model. The significance level was set at $p < 0.05$. The diagnostic accuracy in the form of sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were obtained for predictive CT parameters identified as independent.

Results

Patient characteristics

Out of 131 patients, $n = 36$ had International Federation of Gynaecology and Obstetrics (FIGO classification 1988) stage I–IIB dis-

ease so these were excluded from further analysis. Of the 95 patients with FIGO stage IIC to IV no preoperative CT of abdomen was available in DICOM format for 20 patients. In the remaining 75 patients no macroscopic tumour was achieved in 37.3%, residual tumours from 1–10 mm were present in 34.7%, residual tumours > 10 mm remained in 21.3% and the tumour was not resectable in 5 patients (6.7%) (► **Fig. 1**). The mean age was 63 years (min. 34, max. 81 years, SD 10.4 years). The mean BMI

► **Fig. 2** Cumulative overall survival on ovarian cancer stage IIC-IV (n = 75) depending on the size of the postoperative residual tumour.

was 28 kg/m², and 36% of the women were obese (BMI ≥ 30 kg/m²). 13.3% of the women had a Karnofsky index < 70%. According to the American Society of Anaesthetists (ASA) classification 37.3% had a score of 3. On histopathology, high-grade serous papillary OC was found in 58.7%, while other types occurred much more seldom: low-grade serous OC in 12%, endometrioid OC in 14.6%, clear cell OC in 6.7% and undifferentiated OC in 5.3%. The operative procedure consisted of primary laparotomy in 66.7%, laparoscopy (LSC) with conversion to laparotomy (one-stage) in 20% and laparoscopy with subsequent laparotomy (two-stage procedure within 10 days after LSC) in 13.3%. In 34.7% of the women, a multivisceral operation with partial bowel resection was performed (► **Table 1**).

Survival analysis

The cumulative 5-year overall survival rate was 42.9% for patients with no macroscopic tumour, 26.9% with macroscopic residual tumour 1–10 mm and 4.8% with residual tumour > 10 mm. The median overall survival was significantly higher at 44 months with no macroscopic tumour than with residual tumour 1–10 mm (34 months) and reached 19 months with residual tumour > 10 mm (no residual tumour vs. residual tumour > 10 mm, p = 0.003; residual tumour 1–10 vs. > 10 mm, p = 0.038) (► **Fig. 2**).

CT parameters

Diffuse peritoneal thickening was described preoperatively in 47/75 (62.7%) patients, the CT report found involvement of the greater omentum in 34.7%, pleural effusion and ascites were each described in 32%, and metastases in the mesocolon > 2 cm were

found in 29.3%. Suprarenal lymph nodes > 1 cm were found in 20% and infrarenal lymph nodes > 2 cm in 18.7%. Intraparenchymal liver metastases were detected in 9/75 (12%). All of the five patients with non-resectable tumour had a pleural effusion and four had diffuse peritoneal thickening and metastases in the mesocolon > 2 cm (► **Table 2**).

Macroscopic residual tumour vs. no macroscopic tumour

When the groups macroscopic residual tumour (n = 47) vs. no residual tumour (n = 28) were compared using univariate analysis, the high-grade serous papillary OC histopathological subtype increased the risk, while a BMI ≥ 30 kg/m² tended to be associated with a lower risk of residual tumour (OR 0.38; 95% CI 0.14–1.02; p = 0.051). The following CT parameters were associated with a significantly increased risk of macroscopic residual tumour: diaphragm metastases > 2 cm (p = 0.002), mesocolon metastases > 2 cm (p = 0.004), metastases in the greater omentum (p = 0.007), peritoneal metastases > 2 cm (p = 0.03), ascites (p = 0.002) and diffuse peritoneal thickening (p < 0.001). In the multivariate logistic regression, however, no CT feature was found to be an independent parameter for the endpoint macroscopic residual tumour; only the histopathological subtype high-grade serous papillary OC (aOR 5.5; 95% CI 1.48–20.6; p = 0.011) was identified as an independent parameter (► **Table 3**).

Residual tumour > 10 mm vs. ≤ 10 mm

From the clinical and histopathological parameters no predictor for suboptimal tumour resection (residual tumour > 10 mm) could

be identified; the Karnofsky index ≤ 70% (aOR 5.96; 95% CI 0.99–35.7; p = 0.051) was just below the level of significance. Of the CT parameters, intraparenchymal liver metastases were associated with a significantly increased risk of residual tumour > 10 mm (aOR 8.04; 95% CI 1.53–42.2; p = 0.014). All other CT parameters showed no significant differences when the groups were com-

pared (► **Table 4**). The diagnostic validity of CT with regard to sub-optimal tumour resection thus reaches a sensitivity of 37.5% (95% CI 15.2–64.6) with a specificity 89.7% (95% CI 72.6–97.8), the positive predictive value (PPV) is 66.7% (95% CI 36.6–87.4) and the negative predictive value (NPV) is 72.2% (95% CI 63.6–79.5). The accuracy of the test is 71.1% (95% CI 55.7–83.6).

Prediction of lymph node metastases

The lymph nodes (LN) of 51 patients were assessed by histopathology and $n = 31$ were node-positive. LN metastases were found on histopathology in 9 of 10 women with the CT parameter suprarenal LN > 1 cm. The sensitivity, specificity, PPV and NPV were 29% (95% CI 14.2–48), 94.7% (95% CI 74–99.9), 90% (95% CI 55.3–98.5) and 45% (95% CI 39.3–68.2). In 11 of 12 patients with infrarenal LN > 2 cm in the CT LN metastases were found on histopathology, equivalent to a PPV of 91.7% (95% CI 60.6–99). The sensitivity, specificity and NPV of the parameter were 35.5% (95% CI 19.2–54.6), 95% (95% CI 75.1–99.9) and 48.7% (95% CI 41.8–55.7).

Discussion

The predictive value of preoperative CT of the abdomen in the evaluation of suboptimal cytoreduction in patients with advanced ovarian cancer was the object of this study as patients with no macroscopic tumour have a better prognosis than patients with residual tumour ≤ 1 cm and residual tumour > 1 cm [2, 20]. The aim of no macroscopic tumour and therefore an improvement in overall survival was achieved in 37.3% of women with FIGO stage IIC–IV ovarian cancer. In a retrospective analysis of three studies by the Gynecologic Oncology Group (GOG) of 1895 patients with FIGO stage III, Winter et al. (2007) reported that 23.1% had no macroscopic tumour. In a meta-analysis of the Cochrane database 11 studies were evaluated with regard to the prognostic influence

of postoperative residual tumour. Only six studies contained information about the percentage of patients with no macroscopic tumour and this varied between 28.1 and 86% [21]. Harter et al. showed that by introducing structured quality management the proportion of patients with no macroscopic tumour was increased from 33% up to the year 2000 to 62% between 2004–2008, which was reflected in a significant prolongation of median overall survival from 26 months to 45 months [22]. On the other hand, analysis of a multicentre study of advanced ovarian cancer (GOG 182, $n = 2655$) demonstrated that not all patients benefited from a radical operation with the outcome of no macroscopic tumour. Patients with a high tumour burden initially ($n = 199$) had significantly worse median disease-free survival (18.3 vs. 33.2 months; $p < 0.001$) and overall survival (50.1 vs. 82.8 months; $p < 0.001$) compared with patients with a low to medium tumour burden ($n = 661$) despite complete tumour resection. The authors pointed out the greater postoperative morbidity after complex surgical procedures and concluded that patients with a large initial tumour burden in whom the aim of no macroscopic tumour can be achieved only with high operative risk would benefit more from neoadjuvant chemotherapy [23]. The non-inferiority of primary chemotherapy compared with primary surgical cytoreduction was confirmed in a randomised study by the European Organisation for Research and Treatment of Cancer (EORTC). In this study, patients with stage IIIC and IV ovarian cancer were randomised to two arms,

1. Primary operation, followed by six cycles of platinum-containing chemotherapy or
2. Three cycles of primary chemotherapy, followed by surgery and three more cycles of chemotherapy.

The proportion of patients with no macroscopic tumour was much lower with primary surgery than after neoadjuvant chemotherapy (19.4 vs. 51.2%), but the groups did not differ with regard to the primary endpoints overall survival and recurrence-free survival [3]. Comparable results were also delivered by the prospective randomised non-inferiority CHORUS study with 552 patients with stage III and IV disease, conducted in the UK and New Zealand, in which the median survival after primary operation was 22.6 vs. 24.1 months after neoadjuvant PCT [5]. Based on these studies, the American Society of Clinical Oncology (ASCO) recommended initial evaluation by a gynaecologic oncologist including the preoperative CT of abdomen and pelvis and thorax in women with suspected ovarian cancer of FIGO stage IIIC or IV. Women with a high perioperative risk or low probability of optimal cytoreduction (residual tumour < 1 cm, ideally no residual tumour) should receive neoadjuvant chemotherapy. If optimal cytoreduction (macroscopic freedom from tumour as far as possible) is probable with acceptable perioperative morbidity, primary operative therapy should be favoured [24].

With regard to the endpoint suboptimal tumour resection (residual tumour > 1 cm), the finding of intraparenchymal liver metastases was the only independent predictive parameter. In previous studies, different models were tested for predicting suboptimal tumour resection by CT, some of which also considered clinical and histopathological parameters [12–16, 18, 25–29]. While the different models in the predominantly single-centre retrospective studies could predict suboptimal tumour resection with a sensitivity and specificity each over 80%, confirmation by cross-validation at other institutions or in their own subsequent cohorts was mostly lacking [17, 18]. Only Borley et al. (2014) successfully demonstrated the predictive value of a score they developed in a validation set with 70 patients [30]. This study included the CT parameters lung metastases, pleural effusions and tumour metastases > 10 mm in the mesentery of the small and large bowel as well as infrarenal para-aortic lymph nodes in the predictive model. However, the diagnostic validity of the scores was only moderate (AUC 0.721; 95% CI 0.594–0.847) with a sensitivity of 64.7% and specificity of 67.9%. In our study, the sensitivity of the parameter intraparenchymal liver metastasis was very low at 37.5% though the specificity was high at 89.7% with a positive predictive value of 66.7%. This means that of 10 patients with preoperative evidence of intraparenchymal liver metastases in the CT, roughly seven women have suboptimal tumour reduction but optimal debulking is possible in three patients.

Since the prognostic survival advantages is evident when macroscopic freedom from tumour is achieved [31], more recent studies have defined this as the aim of debulking surgery. Our results show that various CT parameters correlate significantly with the presence of macroscopic residual tumour, including diaphragm metastases > 2 cm, mesocolon metastases, involvement of the greater omentum, ascites and diffuse peritoneal thickening. However, no single CT parameter was identified as an inde-

pendent factor whereas aggressive tumour biology (high-grade serous papillary OC) indicated incomplete tumour resection. On the other hand, patients with low-grade serous papillary OC also benefited from complete tumour resection [32].

In our study diffuse peritoneal thickening in particular correlated with macroscopic residual tumour (OR 6.7; $p < 0.001$). However, 10 of 47 patients with this CT parameter had no macroscopic residual tumour and the residual tumour was > 10 mm in only 12 patients. Borley et al. (2014) also applied their score to the endpoint complete tumour resection vs. residual tumour ≥ 1 mm and showed a sensitivity of 50% with a specificity of 68.4% in the validation set [30]. A recently published study by Chesnais et al. (2017) with the endpoint of macroscopic residual tumour included, besides imaging findings, clinical parameters such as age, weight and paraclinical findings such as CA 12-5 and serum albumin in their analysis of 251 ovarian cancers, 196 with stage III and IV. They established a 100-point score, consisting of the parameters BMI, CA 12-5, CT evidence of tumour in the diaphragm and/or omentum and evidence of parenchymal metastases on positron emission tomography (PET), and used this score to divide patients into three groups: low risk (primary cytoreduction), medium risk (evaluation by laparoscopy) and high risk (neoadjuvant chemotherapy). In patients with advanced ovarian cancer (FIGO stage IIIC–IV, $n = 167$) the probability of incomplete cytoreduction in the high-risk group was 89.5% (77/86; 95% CI 81.3–94.4). Only six patients were assigned to the low-risk group, however, and three of them had complete tumour reduction [28]. Interestingly, in our study, clinical parameters such as age, BMI, Karnofsky index and ASA stage had no influence on operability.

Other imaging modalities such as PET-CT and magnetic resonance imaging (MRI) may be of benefit in predicting lymph node metastases (PET-CT) and local tumour spread in the pelvis (MRI), but studies currently do not justify their routine use in staging ovarian cancer [8].

In a comprehensive review that included different definitions of the endpoint optimal tumour reduction, Gomez-Hidalgo et al. (2015) contrasted various imaging studies with those of staging laparoscopy [33]. The rationale for primary laparoscopy is the possibility of obtaining tissue for histological and molecular genetic tests and in the identification of patients in whom optimal tumour reduction is not possible and who will therefore benefit from neoadjuvant chemotherapy. Fagotti et al. showed for the first time in 2005 that laparoscopy can predict optimal cytoreduction with an accuracy of 90% and demonstrated the superiority of laparoscopy when compared with clinical radiological findings in the negative predictive value (100 vs. 73%) [34]. In subsequent studies, the same team established a laparoscopic score for predicting suboptimal tumour reduction and confirmed its validity in prospective single-centre and multicentre studies [35, 36]. In a recent Cochrane analysis, the validity of laparoscopy in predicting optimal tumour reduction (no macroscopic residual tumour or residual tumour ≤ 1 cm) was investigated. In the included 18 studies, between 16 and 73% of the women were assessed laparoscopically as not optimally resectable. Optimal tumour reduction was predicted for the remaining 27 to 84%. In the subsequent debulking operation residual tumours > 1 cm remained in 0 to 31%, i.e., these women could have been spared the primary operation. A

pooled analysis was not possible because of the heterogeneity of the data. Only two of the 18 studies included information on the false-positive rate, that is, laparoscopic assessment of suboptimal tumour reduction was followed by debulking surgery with resulting residual tumour ≤ 1 cm [37].

New importance is attached to the preoperative assessment of pelvic and para-aortic node status as a result of the recently published LION study [19]. According to this, patients with advanced ovarian cancer and clinically and radiologically unremarkable nodal status do not benefit from systematic lymphadenectomy. According to our study, however, the negative predictive value of the CT with regard to nodal status is similarly low as in the recent retrospective analysis by Widschwendter et al. (2020) [38]. However, we found a high positive predictive value of over 90%, i.e., the finding of enlarged LN in the CT could be relevant for preoperative (up-)staging of early tumour stages and thus for treatment planning.

The limits of the present study are the retrospective study design. The case number was reduced markedly by the lack of a preoperative CT in 20 patients. Besides the lower statistical power, this also signifies the risk of bias through selection of patients with particularly good or poor operability. The strengths are the blinded review of the CT scans by an oncological radiologist and that the study was conducted in a large gynaecologic oncology centre. Along with a high number of patients, the quality of treatment is reflected in the 5-year survival rates, which are comparable with those of other centres.

Conclusion

Our study emphasises the necessity in advanced ovarian cancer of resecting the tumour as completely as possible. Prediction of incomplete tumour resection is not always possible with certainty by imaging methods. However, various CT parameters such as extensive tumour metastases in the diaphragm and/or root of the mesentery, intraparenchymal liver metastases as well as diffuse peritoneal thickening indicate suboptimal tumour reduction and justify explorative laparoscopy with the possibility of continuing as debulking surgery. Ultimately, the assessment of operability is dependent to a high degree on the surgeon's expertise, so treatment at a certified gynaecologic oncology centre is necessary.

Acknowledgements

The authors are indebted to Dr. Jens Voigt, radiologist, for skillful review of the computed tomograms. They also wish to thank Prof. Günther Kundt of the Institute of Biostatistics and Informatics in Medicine, University of Rostock for his generous advice on statistical analyses.

Conflict of Interest

The authors declare that they have no conflict of interest.
