A 14-month-old girl was admitted to our department because of repeated nonbilious vomiting for >3 months and malnutrition. Upper gastrointestinal radiography showed partial obstruction of the duodenum (Fig. 1). Gastroscopy confirmed a membranous duodenal stenosis with an opening of about 3 mm in diameter, and no view of the duodenal papilla above the membrane (Fig. 2a). We performed both balloon dilation and membrane resection (Video 1).

First, endoscopic balloon dilation was carried out to locate the duodenal papilla (Fig. 2b), which was in the 10 o’clock position and 1 cm below the membrane (Fig. 2c). Then, following submucosal injection of diluted epinephrine (1:10 000), a circumferential incision was performed contralaterally to

the duodenal papilla using an insulated-tip knife (▶Fig. 2d,e). The resected membrane was removed and the opening was increased to 12 mm in diameter (▶Fig. 2f). A nasojejunal tube was inserted through the opening. The girl recovered uneventfully after endoscopic treatment, and symptoms of vomiting gradually disappeared. Pathological examination showed that muscle tissue was present in the resected membrane (▶Fig. 3).

Membranous duodenal stenosis is a common pediatric gastrointestinal abnormality, with an incidence of 1:10 000–40 000 [1], which has traditionally been managed either via laparotomy or laparoscopic surgery. Endoscopic treatment of sporadic cases has been reported [2–4]. However, balloon dilation alone, without membranectomy, may result in stricture recurrence, whereas membranectomy cutting techniques cannot completely avoid possible injury to the duodenal papilla or even perforation, especially if the duodenal papilla is below the membrane. Given the limited space and thinner duodenal wall in children, submucosal injection prior to membrane resection would help to avoid cutting too deeply and ensure safe removal of the lesion.
