A 70-year-old gentleman was admitted with a suspected gastric submucosal tumor (SMT) detected by abdominal contrast computed tomography (CT) (▶Fig. 1) to investigate his complaints of dull pain in the abdomen. Preoperative endoscopic ultrasonography (EUS) helped to confirm and locate the lesion after repeated esophagogastroduodenoscopy revealed nothing (▶Fig. 1). Endoscopic intraperitoneal subserosal dissection technique was employed in this case. Details of the steps are shown in ▶Fig. 2 and ▶Video 1, including mucosal incision, submucosal tunneling, intraperitoneal subserosal dissection, removal of the lesion, and mucosal closure. The pathological diagnosis was gastrointestinal stromal tumor (GIST) (WHO, Digestive System Tumours, 5th edn.), prognostic group 1. Intravenous antibiotics were given for 1 day after operation. The gastric tube was removed on postoperative day (POD) 2, fluid diet was resumed on POD3, and on POD7 the patient was discharged.

For smaller SMTs deriving from muscularis propria, endoscopic full-thickness resection (EFTR) has comparable feasibility, safety, and effectiveness to surgical resection, and, more specifically, quicker recovery, and lower costs [1,2]. However, for SMTs with a predominantly extraluminal growth pattern, EFTR is sometimes difficult to perform because of the high mobility of the tumor and the limited view from the gastric cavity. The submucosal tunneling endoscopic resection technique is suitable for predominantly extraluminally growing SMTs [3], but its use is sometimes limited by the location of the lesion. When the tumor lies in an angled position such as the lesser curvature of the antrum, as in the present case, or the greater curvature of the corpus, difficulty arises in creating a submucosal tunnel towards it. To overcome these disadvantages, our recently reported new technique, called endoscopic intraperitoneal subserosal dissection, offers a potential solution in such a case [4]. How to locate the lesion precisely also remained a problem, when the small tumor could not be observed under esophagogastroduodenoscopy. CT provides little reference, for the anatomic landmarks in tomographic imaging differ from those under esophagogastroduodenoscopy. CT provides little reference, for the anatomic landmarks in tomographic imaging differ from those under esophagogastroduodenoscopy, and the relative position would alter depending on the gastric inflation status. Subsequently, EUS-guided clip anchoring [5] was attempted and proved highly successful. In conclusion, endoscopic intraperitoneal subserosal dissection on the basis of EUS-guided anchoring is an effective solution for treating SMTs with a predominantly extraluminal growth pattern which are invisible under esophagogastroduodenoscopy.
