Abstract:

Objective
The aim of this study is to investigate whether a history of spontaneous preterm birth (SPTB) is associated with maternal depressive and anxiety symptoms, or psychosocial distress in the fifth decade of life.

Study Design
This is a secondary analysis of the PreCaris study, a prospective observational study in which we included 350 women with a history of SPTB between 22+0 and 36+6 weeks of gestation and compared them to 115 women who had a term birth. Primary outcomes were the Depression and Anxiety scores measured using the Hospital Anxiety Depression Scale and Psychosocial distress assessed with the Distress Thermometer for Parents. Secondary outcomes were self-reported impact of the birth in daily life and psychosocial support after delivery.

Results
After a median of 13 years after delivery, no significant differences were found in primary outcomes. Significantly more women with a history of SPTB reported that the birth still had impact in daily life; aOR 2.46, (95% CI: 1.35–4.48). A total of 57 (16.3%) women after SPTB reported to have needed professional psychosocial support after delivery but did not receive it. These women more often had a high Anxiety-score (p=.030), psychosocial distress (p=.001) and influence of birth in daily life (p=.000).

Conclusion
There are no long-term effects on depressive and anxiety symptoms and psychosocial distress in women who experienced SPTB compared to women who had a full-term pregnancy. A significant part of the women who delivered preterm needed psychosocial support but did not receive it and were at higher risk of anxiety, psychosocial distress and impact in daily life. We therefore recommend offering all women after SPTB psychosocial support after delivery.

Spontaneous preterm birth; Depression; Depressive symptoms; Anxiety; Psychosocial distress.

Introduction
Preterm birth (PTB) remains a significant challenge in the field of obstetrics, as it continues to be the leading cause of neonatal morbidity and mortality globally [1]. According to the estimates from 2014, approximately 14.8 million infants, accounting for 10.6% of all live births worldwide, were born prematurely [2]. Spontaneous preterm birth (SPTB), characterized by delivery before 37 weeks of gestation due to either spontaneous contractions with intact membranes or spontaneous rupture of the membranes, accounts for approximately 65-75% of all preterm births [3].

PTB is associated with short term complications, including respiratory distress syndrome, intraventricular haemorrhage and necrotizing enterocolitis as well as long-term consequences, such as neurocognitive impairment, [4,5]. Previous studies have shown that mothers of these children are at greater risk of psychological distress than mothers of term infants during infant hospitalization [6,7]. These elevated levels of maternal psychological distress may continue for months or even 2 years after hospital discharge [8-12]. Bener et al. showed that depression (29.4% vs. 17.3%) and anxiety (26.5% vs. 11.6%) were significantly more common among women with a SPTB compared to term birth within 6 months postpartum [9]. In addition,
Bozette et al. found that 16% of the mothers had elevated depressive symptoms when their children were 3 years of age [13].

Overall, having a preterm child appears to influence parental mental health, stress, and family functioning during early childhood. However, very little attention has been paid to long term influence of preterm birth on the experience of psychological distress in women later in life. Treyvaud et al. showed that parents of preterm born children (GA <30 weeks or birth weight <1250 grams) reported higher levels of anxiety, depression symptoms and levels of parenting stress seven years after birth [14]. Bener et al. found a negative influence on the psychosocial and/or work environment of parents, 19 years after the preterm birth of their child [9]. However, this study is published in 2013 and based upon a cohort from 1983.

It is hypothesized that SPTB can cause stress, anxiety, and uncertainty in parents, both directly after pregnancy but also in the rest of their life [15]. The aim of our study was to investigate whether women with a history of SPTB had higher scores for depressive and anxiety symptoms 9 to 16 years after pregnancy.

Methods
This is a secondary analysis of the PreCaris study, a prospective observational study in which we included women with a history of SPTB, the cases, and compared them to women who had a term birth, the controls. SPTB was defined as preterm birth between 22+0 and 36+6 weeks starting with spontaneous contractions or spontaneous rupture of membranes. A history of term birth was defined as giving birth at or after 37+0 weeks of gestation. The full list of exclusion criteria is provided in Supplementary Information 1. Medical records were screened for in- and exclusion criteria and eligible women were invited. All participants gave written
informed consent prior to their inclusion in the study and received cardiovascular risk assessment at the Amsterdam UMC, location VU Medical Center and filled out questionnaires about physical and mental health.

Approval for the study was obtained from the medical ethics committee of the VU University Medical Center in Amsterdam and from the hospital board of the Academic Medical Center Amsterdam (protocol approval: NL38972.029.12).

Measures

Maternal mental health was assessed with the Hospital Anxiety and Depression Scale (HADS). The HADS is a 14-item self-report questionnaire, designed for screening of depressive and anxiety symptoms in non-psychiatric patients [16]. The HADS is divided into two subscales: the depression (HADS-Depression) and anxiety subscale (HADS-Anxiety), both consisting of 7 items. The item scores range from 0 to 3, therefore the scores of the anxiety and depression scales range from 0 to 21. A higher score indicates more depressive or anxiety symptoms. Maternal psychosocial distress was measured by the Distress Thermometer for Parents (DT-P), which is a well-validated, brief screening instrument that is used in clinical practice in the Netherlands to identify distress and everyday problems in parents of children with a chronic condition [17]. The DT-P ranges from 0 to 10, with a cut-off score of 4 for psychosocial distress, which consist of 29 individual items that reflect everyday problems in five domains (practical, social, emotional, physical, and cognitive). For each item, participants could indicate with “yes” or “no” if they experienced any of the problems in the last week, by which we could identify the sources of psychosocial distress.
We also asked whether the (spontaneous preterm) birth and events around it still have impact on daily life, which could be answered with “yes” or “no”. When answered with yes, participants could write down their explanation in an open text block. The answers were subdivided in four categories by 2 independent investigators: being too protective to your child, concerns about a disabled child, psychosocial problems, or a positive influence of the (preterm) birth. Next to that, we asked whether participants received psychosocial support after delivery which could be answered with “yes” or “no and I did not need it” or “no but I needed it”.

Outcomes
The primary outcomes were the median HADS-Depression and HADS-Anxiety scores, and psychosocial distress, defined as a score ≥ 4 on the DT-P [17]. We also investigated the incidence of elevated depressive symptoms which was defined as a HADS-Depression score ≥ 11 and elevated anxiety symptoms defined as a HADS-Anxiety score ≥ 11, which indicates a suspected moderate-to-severe elevation [16]. Secondary outcomes were the incidence of impact of (spontaneous preterm) birth in daily life and psychosocial support after delivery.

Statistical analysis
Patient characteristics were examined using Chi-square test, Fisher’s exact test, independent samples t-test or Mann-Whitney U-test. All calculations to obtain corresponding p-values were two-sided. The characteristics for continuous variables were presented as mean and standard deviation (SD), variables with a skewed distribution as median and interquartile range [IQR]. Categorical variables were presented as percentages of numbers for corresponding group. A multivariable analysis was performed to adjust for potential confounders using hierarchical backward elimination, including covariates that were
moderately associated with preterm birth (p<0.1). We performed a subgroup analysis based upon the severity of SPTB: extreme (22+0 – 27+6 weeks of gestation), very (28+0 – 31+6 weeks of gestation) and moderate preterm (32+0 – 36+6 weeks of gestation) and based upon birth weight: <1000g, 1000-1500g and 1500-2500g. In all analyses, a p-value <0.05 was considered statistically significant. Data were analysed using SPSS 22 software (Chicago, IL).

Results

In our original trial, a total of 350 cases and 115 controls underwent risk assessment, see the flowchart in Figure 1. Baseline characteristics at index pregnancy are shown in Table 1. Cases were on average one year younger than controls (p=.039). Most of the cases delivered moderate preterm. Years of follow-up and mean age was comparable between the groups. More cases were Caucasian (p=.011) and had a low education compared to controls (p=.010). There were no significant differences in obstetric history between the groups, see Table 2.

The questionnaire results are shown in Table 3. Median HADS-Depression and HADS-Anxiety score did not differ between the groups. NICU admission, neonatal death, and previous PTB were not associated with HADS-scores. Psychological distress was present in approximately half of the cases and controls (p=.365). Mean distress scores on practical, social, emotional, physical, and cognitive level did not differ between the groups. NICU admission and neonatal death were not associated with psychosocial distress.

Significantly more cases reported that the birth still has impact in daily life. NICU admission and neonatal death significantly influenced the risk of experiencing impact in daily life (aOR 3.42; 95% CI 1.58 – 7.41). Of these women, most reported psychosocial problems (n=51, 59.3%), such as panic attacks, depression, sleeping problems and recurrent thoughts of the (preterm) birth. Others mentioned problems in taking care of their disabled child (n=12,
12.9%) and being too protective to their child (n=10, 10.8%). However, not only negative impact was mentioned; 13 cases (14.0%) indicated that the preterm birth changed them into the person they are today, which had a positive outcome in their daily life, including less worrying about the little things and more feelings of strength, proudness, and thankfulness for life.

Among cases, a total of 75 (21.4%) women received professional psychosocial support after delivery, which was significantly more compared to controls (p=<.001). Women with an extreme PTB received psychosocial help most often (n=33, 40.2%) compared to very (n= 28, 25.9%) and moderate preterm birth (n=14, 8.8%, p=<.001). Psychosocial support was more often given to participants experiencing neonatal loss (n=17, 43.6%) compared to participants with a living infant (n=66, 15.5%), p=<.001. Among cases, most (n=44, 58.7%) received psychosocial support from medical social workers during their stay in the hospital. Psychosocial support was less often given by a psychologist (n= 25, 33.3%) or psychiatrist (n=6, 8.0%).

A total of 57 (16.3%) cases reported to have needed professional psychosocial support after delivery but did not receive it, consisting of 8 (9.8%) extreme preterm, 20 (18.5%) very preterm and 29 (18.1%) moderate preterm birth (p=.079). Neonatal death occurred in 3 (5.3%) cases and did not significantly alter the results. Women that needed psychosocial help but did not receive it, had elevated HADS-Anxiety scores (p=.030), reported more psychosocial distress (p=.001), and influence in daily life (p=.000).

Sub analysis showed that a history of extreme preterm birth was associated with higher impact of birth in daily life compared to term birth. A history of very preterm birth was
associated with elevated HADS-Anxiety scores and impact in daily life, see Table 4. Neonatal death did not significantly alter the results. Sub analysis based on birth weight is shown in Table 5. After adjusting for neonatal death, birth weight between 1000 and 1500g remained strongly associated with self-reported impact in daily life (aOR 4.06, 95% CI 2.20 – 7.48).

Discussion

This observational cohort study investigated the long-term effects of SPTB on maternal mental health and psychosocial distress 9 – 16 years after pregnancy. After a median follow-up time of 13 years after SPTB we found that depressive, anxiety symptoms and psychological distress were comparable to women after a term delivery. Yet, elevated anxiety scores were more common among women who delivered very preterm. A history of SPTB was significantly associated with impact of the birth and events around it in daily life, which was reported most often among participants with a history of extreme preterm birth and birth weight between 1000 and 1500g.

HADS-Depression and HADS-Anxiety scores were comparable with normative data in the Dutch population [18]. The incidence of moderate-to-severe elevated depression symptoms was low in both cases and controls, and comparable with the study of Yaari et al. [19]. Our results differ from the previous study performed by Treyvaud et al. which found higher levels of depression and anxiety, 7 years after delivery [14]. The differences could be explained by the longer follow-up period of our study which was median 13 years compared to 7 years in the study of Treyvaud et al. In contrast, we not only included women with extreme preterm birth and low birth weight, but all women with a history of spontaneous preterm birth. It is hypothesized that infants born extremely preterm or with low birth weight are often hospitalized in the NICU and are therefore at high risk for complications and mortality, suggesting that these mothers had a more traumatic and stressful postpartum period which
leads to higher HADS-scores. In our sub analysis, we found that a history of very preterm and not extreme preterm birth was significantly associated with elevated HADS-Anxiety. Birth weight was, after adjustment for neonatal death, not significantly associated with HADS-scores. This could be explained by the fact that mothers tend to experience resilience and posttraumatic growth after a traumatic event, which leads to lower HADS-scores among women with extreme preterm birth and birth weight below 1000g on the long term [20-22]. Psychosocial distress in both cases and controls was comparable with the incidence of distress in the Dutch female population [18]. In contrast to what we expected, sub analysis showed that the severity of SPTB and birth weight were not associated with psychosocial distress, although their infants are at higher risk for chronic conditions later in life. Our findings could be explained by the fact that late preterm infants primarily develop cognitive and behavioural problems [22,23]. These problems may be identified only later in life, during late childhood or adolescence, when social and academic demands increase. This could influence the maternal distress level on the long-term, because studies suggesting that the quality of life of mothers is associated with the child’s mental health and peer relationships and not particularly with the child’s disabilities [24]. This explanation, together with the resilience and posttraumatic growth as mentioned before, is in line with our results suggesting that NICU admission and neonatal mortality were not predictive for elevated HADS-Depression, HADS-Anxiety, and psychosocial distress 13 years after SPTB.

In our study, a history of SPTB was significantly associated with impact of the birth and events around it in daily life. This is in line with previous studies, finding a significant family impact after preterm birth [14,25,26]. Our results showed that GA, neonatal birth weight, NICU admission and neonatal death were strongly predictive for experiencing impact of the birth in daily life. This is in line with other studies, finding a higher impact in families of very
low birth weight children who had high neonatal medical risk, compared to low neonatal medical risk [27-29]. Additionally, it is possible that these women still show symptoms of post-traumatic stress disorder (PTSD), given their traumatic experiences perinatal and early postpartum [12]. Our results showed that SPTB was associated with feelings of sadness and recurrent thoughts about the birth, which is suggestive for PTSD.

A total of 75 (21.4%) participants received psychosocial support after delivery, which was most often given by a medical social worker. In the participating hospitals of this study, it was not standard care to offer psychosocial support after delivery. Among cases, 1 out of 6 reported to have needed psychosocial support after delivery but did not receive it. The incidence of elevated HADS-scores was higher among these cases, as they reported more psychosocial distress, and negative impact of their child’s (pre)term birth in daily life.

Strengths and limitations

This is the first study that investigated maternal mental health and psychosocial distress on the long-term in the overall group of women who experienced a SPTB, regardless of birth weight in comparison to a history of term birth. We performed a sub analysis to assess the influence of GA and birth weight on the HADS-Depression, HADS-Anxiety, and psychosocial distress. In addition, we performed an extensive assessment in a large cohort with a total of 465 participants.

Our study had some limitations that should be addressed. We did not adjust for the potential confounder prenatal or perinatal depression and neurodevelopmental disabilities of the child since it was outside the scope of the initial research. A history of depression and anxiety are known risk factors for developing PTB and neurodevelopmental disabilities are a strong
predictor of maternal mental health, distress, and impact in daily life [30,31]. Furthermore, impact in daily life was measured based on one single question, where participants could indicate “yes” or “no”. It was not measured with a validated questionnaire. Finally, the HADS and DT-P were filled out based on how participants felt the past week. Therefore, short-term mood variations could have led to a distorted view of the long-term effects on maternal mental health and psychosocial distress.

Risk assessment of our study was 9 – 16 years after their index pregnancy. Even though follow-up period did not differ between cases and controls, the guideline for active treatment of extremely preterm infants in the Netherlands was modified twice during the study period. In 2006, the guideline changed to active treatment of infants born by 25+0 weeks and in 2010 lowered to 24+0 weeks of gestation. Active treatment lowers neonatal death and could therefore influence HADS and DT-P scores, both in a negative and positive way.

**Conclusion**

In conclusion, there are no long-term effects of SPTB on maternal depressive and anxiety symptoms and psychosocial distress 13 years after pregnancy. However, a history of SPTB was significantly associated with higher impact of birth in daily life, especially in mothers of children who were born extreme preterm and with a low birth weight. A significant part of the women who delivered preterm needed psychosocial support but did not receive it. This subgroup was at higher risk of developing anxiety symptoms, psychosocial distress, and reported more often impact of birth in daily life. We therefore recommend offering psychosocial support after delivery to all women after SPTB.
