Conflict of Interest: The authors declare that they have no conflict of interest.

Abstract:
Background and study aims: Until recently, autoimmune gastritis (AIG) was usually diagnosed at late stages based on typical endoscopic findings, including corpus-dominant advanced atrophy. Early-stage AIG prior to complete gastric atrophy had rarely been diagnosed due to a lack of knowledge about its endoscopic characteristics. The present study sought to identify the endoscopic characteristics of early-stage AIG, enabling its early diagnosis.

Patients and methods: The clinical and endoscopic findings of 12 patients diagnosed with early-stage AIG between 2016 and 2021 were retrospectively evaluated. Patients were included if they were (1) positive for serum anti-parietal cell antibody, (2) diagnosed with histological early-stage of AIG, and (3) endoscopically positive for folds on the greater curvature of the gastric corpus. Results: Two characteristic endoscopic findings of early-stage AIG were identified: longitudinal alignment of pseudopolyps (i.e., a bamboo joint-like appearance) and swelling of gastric areas with erythema (i.e., a salmon roe-like appearance).

Conclusions: Endoscopic findings characteristic of early-stage AIG include a bamboo joint-like appearance and a salmon roe-like appearance. Studies in large numbers of patients with long-term follow-up are needed to confirm these findings.

Introduction

Autoimmune gastritis (AIG) is a type of chronic atrophic gastritis, in which immune-mediated destruction of fundic glands progresses towards severe gastric atrophy. AIG was previously considered a rare disease in Japan due to the low prevalence of pernicious anemia [1,2]. More recently, however, reports of AIG have increased in Japan [3,4], with a prevalence approaching that in western countries. Until recently, AIG was usually diagnosed during later stages based on typical endoscopic findings, including corpus-dominant advanced atrophy [3,4]. Although histopathological evaluation has shown that AIG progresses from early to end stage [5], early-stage AIG has rarely been diagnosed prior to complete gastric atrophy, due to a lack of knowledge about its endoscopic characteristics. Several patients were recently diagnosed histologically and serologically with early-stage AIG [6-11]. Since then, additional patients have been diagnosed with AIG before complete gastric atrophy. Eradication therapy in Helicobacter pylori (H. pylori)-positive patients and steroid treatment in H. pylori-negative patients may halt its progression, or even cure this condition [12-14]. Although diagnostic criteria for AIG in Japan, including early-stage AIG, have been proposed, endoscopic findings of early-stage AIG were not included in the criteria [15]. The present study sought to identify the endoscopic characteristics of early-stage AIG, enabling its early diagnosis.
Methods

Diagnostic criteria for early-stage AIG

The Japanese diagnostic criteria for AIG have recently been established [15], but the endoscopic findings for early-stage AIG were not part of these criteria. According to the proposed criteria, histological findings and gastric autoantibody positivity are required for the diagnosis of early-stage AIG. Histological findings of early-stage AIG were specified as follows: the parietal cell / mucous neck cell layer of the oxyntic glands is preserved without interruption; the remaining parietal cells exhibit degeneration and pseudohypertrophy; lymphocytic infiltration is observed between the oxyntic glands; and hyperplasia of enterochromaffin-like (ECL) cells is not always present.

Patients

The clinical and endoscopic characteristics of patients diagnosed with AIG prior to complete gastric atrophy between 2016 and 2021 were retrospectively reviewed. Patients were included if they were (1) positive for serum anti-parietal cell antibody (PCA), (2) diagnosed histologically with early-stage AIG, and (3) endoscopically positive for folds on the greater curvature of the gastric corpus. Patients were excluded if endoscopy revealed severe gastric atrophy with marked vascular visibility and disappearance of folds, which is the most common endoscopic feature in advanced-stage AIG patients [4]. None of these patients had a history of long-time use of proton
pump inhibitors (PPI).

**Laboratory tests**

Serum PCA concentrations were assessed by an indirect immunofluorescence test, with titers \( \geq 1:10 \) considered positive. Serum gastrin concentrations were measured by radioimmunoassay (normal range: <200 pg/mL). Serum concentrations of anti-\( H. \text{pylori} \) antibody (\( H. \text{pylori Ab} \)) were measured by enzyme-linked immunosorbent or latex immunoturbidimetric assays. \( H. \text{pylori} \) infection status was defined as (1) uninfected in patients with no history of \( H. \text{pylori} \) eradication and \( H. \text{pylori Ab} < 3.0 \) U/mL, (2) previously infected in patients with a history of \( H. \text{pylori} \) eradication, (3) currently infected in patients with no history of \( H. \text{pylori} \) eradication and a \( H. \text{pylori} \) Ab titer of \( \geq 10 \) U/mL, or (4) indeterminate in patients with no history of \( H. \text{pylori} \) eradication and \( H. \text{pylori Ab} 3.0-9.9 \) U/mL. Uninfected or currently infected \( H. \text{pylori} \) status was confirmed based on endoscopic findings [16].

**Assessment of endoscopic appearance**

The patients in this study had undergone endoscopy at six institutions: Uji-Tokushukai Medical Center, Sakaide City Hospital, Tokushima Health Screening Center, Kawasaki Medical School General Medical Center, Junpukai Health Maintenance Center, and Junpukai Health Maintenance Center-Kurashiki. Endoscopic images were retrospectively re-evaluated by three
endoscopists (T.K., M.A., and K.H.). The presence or absence of gastric mucosal atrophy was assessed in the antrum and the lesser and greater curvature of the corpus. The Kimura-Takemoto classification [17] was not used because the atrophic border could not be clearly determined in most patients in the present study. Associated local endoscopic findings were also evaluated.

**Histopathological evaluations**

Biopsy specimens were obtained from the greater curvature of the upper or middle corpus in all 12 patients and from the greater curvature of the antrum in 8 of 12 patients, and histological gastritis was assessed by an expert pathologist (R.K.) according to the updated Sydney system [18]. Pseudopyloric metaplasia was examined in 10 patients together with immunostaining for MUC6 and pepsinogen I. Patients were diagnosed with histological early-stage AIG based on the presence of persisting oxyntic glands damaged by lymphocytic infiltration, and pseudohypertrophy of the remaining parietal cells [15] (see representative image in Figure 1). All of these patients were positive for linear or nodular hyperplasia of ECL cells, as shown by immunostaining for chromogranin A, confirming the diagnosis of AIG. Biopsy specimens were taken from pseudopolyps of five patients, with findings in these specimens being histologically consistent with oxyntic mucosa pseudopolyps [19,20,21].

**Statement of Ethics**
This study was conducted in accordance with the guidelines of the Declaration of Helsinki. The study protocol was reviewed and approved by the Ethics Committees of Uji-Tokushukai Medical Center (approval number TGE01906-007) and Kawasaki Medical School (approval number 5178-01). Written informed consent was obtained from each participant.

Results
Clinical profiles
The present study enrolled 12 patients, seven men and five women, of mean age 56.2 years (range: 41-71 years) (Table 1). Most of these patients underwent endoscopy as part of their health checkups, with reasons for endoscopy including a previous history of vitamin B\textsubscript{12} deficiency, iron deficiency anemia, and abnormal serum pepsinogen (PG) levels. Serum PCA titers were ≥1:160 in 11 patients, with one having a PCA titer of 1:80. Serum gastrin levels (mean: 1350.1 pg/mL) were <1000 pg/mL in six patients. Evaluation of \textit{H. pylori} infection status showed that eight patients were uninfected, three were previously infected, and one was indeterminate. None of the patients was currently infected. Three patients had accompanying autoimmune diseases, including two with Basedow’s disease, and one with type I diabetes. Case reports of seven of these patients have been published [6-8,10,11].

Endoscopic findings and histopathological evaluations
Endoscopic findings of the 12 patients, including the extent of endoscopic gastric atrophy and associated local appearances, are summarized in Table 1. Histopathological evaluations of gastritis are summarized in Table 2.

Endoscopically, three patients showed no atrophic changes in either the antrum or corpus. Corpus atrophy was observed in the other nine patients, seven of whom showed no atrophy in the greater curvature of the corpus and six of whom showed no atrophy in the antrum.

Histologically, among 12 patients, no gastric atrophy of the corpus was observed in eight patients and mild atrophy was observed in four. Inflammation was mild in two patients, moderate in nine, and severe in one. Among eight patients studied, mild atrophy or inflammation of the antrum was observed in two patients, who had been previously infected with *H. pylori*. Pseudopyloric metaplasia was present in all of the 10 patients studied, while intestinal metaplasia was absent in all of the 12 patients.

Multiple pseudopolyps were detected in seven patients (Figure 2). These pseudopolyps were longitudinally aligned in rows along the long axis of the gastric corpus, which had a bamboo joint-like appearance. Swollen folds were incompletely segmented by shallow furrows in two patients, showing a bamboo joint-like appearance (Figure 3b). Thus, a total of nine patients presented endoscopically with a bamboo joint-like appearance.

Edematous mucosa with enlarged gastric areas and erythema, called a salmon roe-like
appearance, was observed in non-atrophic areas of the gastric corpus in seven patients (Figure 3). Histologically, these enlarged gastric areas exhibited persisting oxyntic glands damaged by lymphocytic infiltration. Four of these patients also presented with a bamboo joint-like appearance (Figure 3b).

One patient with a previous history of vitamin B$_{12}$ deficiency was suspected of having AIG, despite presenting with a normal endoscopic appearance (Figure 4a, b, c) and lacking any of the characteristic endoscopic findings (Patient 1 in Table 1). A diagnosis of early-stage AIG in this patient was confirmed by histopathological findings (Figure 4d) and a high titer of PCA.

Discussion

To our knowledge, this study is the first to evaluate the endoscopic characteristics of patients with early-stage AIG. Two endoscopic findings were found in patients with AIG prior to complete gastric atrophy: longitudinal alignment of pseudopolyps (called a bamboo joint-like appearance) and swelling of gastric areas with erythema (called a salmon roe-like appearance).

The first clues, by which patients were suspected of having AIG, are shown with a gray background in Table 1. Endoscopic findings were the first clues in 11 patients, with the possibility of AIG suggested by a combination of a bamboo joint-like or salmon roe-like appearance in the corpus and non- or slightly atrophic antrum. Since these endoscopic findings are uncommon in patients with $H. pylori$ gastritis, they could have potential for the endoscopic
detection of early-stage AIG. When AIG is suspected based on endoscopic findings or hematological abnormalities, histological and serological studies are required. Although one biopsy from the greater curvature of the upper corpus is generally considered sufficient, an additional biopsy from the antrum is recommended [15].

Oxyntic mucosa pseudopolyps are a type of remnant oxyntic mucosa spared from atrophic changes in advanced AIG [4,19,20,21]. These pseudopolyps are usually scattered on a background of atrophic mucosa in the proximal corpus and fundus of patients with advanced AIG. In the present study, these pseudopolyps were longitudinally aligned in the greater curvature and the anterior wall of the corpus. They resembled the bamboo joint-like appearance associated with Crohn’s disease, in which swollen longitudinal folds traversed by erosive fissures are observed in the lesser curvature of the proximal stomach [22,23]. Histologically, the bamboo joint-like appearance in patients with Crohn’s disease is characterized by edematous stroma of the lamina propria [22], which is different from the oxyntic mucosa pseudopolyps observed in the present study. In one patient, the pseudopolyps were not sessile but semi-pedunculated, mimicking fundic gland polyps, although they were histologically consistent with oxyntic mucosa pseudopolyps (Figure 2b). A case report showed that pseudopolyps initially seen along the gastric folds in the corpus disappeared after 3 years, accompanied by regression of the folds [24]. Thus, pseudopolyps in the gastric corpus presenting with a bamboo joint-like
appearance could be an endoscopic manifestation of early-stage AIG in patients with ongoing gastric atrophy.

Swelling of gastric areas with erythema was observed in seven patients, and these areas had a salmon roe-like appearance that resembled the snakeskin (mosaic) pattern reported previously [25], which is a characteristic of portal hypertensive gastropathy (PHG) and also referred to as red colored caviar-like gastritis [26]. The salmon roe-like appearance also resembles the diffuse redness in H. pylori gastritis with current infection [27,28]. None of these seven patients had portal hypertension or active H. pylori infection at the time of endoscopy: four were uninfected, one had been previously infected, and one was indeterminate. However, it may be difficult to observe a salmon roe-like appearance in AIG patients with active H. pylori infection.

Endoscopically, the antrum was atrophic to some extent in three of the nine patients with corpus atrophy. These findings are consistent with those of a previous study of advanced AIG [4], in which less than half of the cases showed normal coloration of the antral mucosa. Since, in the present study, two patients had a previous H. pylori infection and infection status was indeterminate in one, the antrum could have been affected by the previous infection of H. pylori as well as by bile reflux.

Serum PCA was strongly positive in 11 of these patients, with titers ≥1:160. A recent retrospective study of patients with histologically proven AIG showed that their mean PCA titer
was significantly higher during the early or florid phase than during the end phase [29],
suggesting that the progressive destruction of parietal cells and the resultant decrease in the
 targeted proton pumps could lead to a reduction in PCA titer. The high PCA titers in the present
study indicated that these patients retained sufficient parietal cells to be targeted
by lymphocytes, a finding confirmed histopathologically. This hypothesis may be confirmed by
long-term follow-up of these patients.

This study had several limitations. First, it was a retrospective study that did not include a
control group. Second, the sample size was small, suggesting that the endoscopic findings in
these patients may not be indicative of the overall endoscopic findings in patients with early-
stage AIG. Other limitations included the use of original selection criteria and the lack of
follow-up of all included patients. Although there was a considerable risk of selection bias in
the present study, as stated above, an analysis employing a large sample size without selection
bias may be impossible due to the rarity of AIG.

In conclusion, the present study suggested that the endoscopic findings observed in this series of
patients, including bamboo joint-like and salmon roe-like appearances, could be characteristic
of early-stage AIG. Studies in large numbers of patients with long-term follow-up are needed to
confirm these findings. These results may contribute to determining the overall endoscopic
characteristics associated with early-stage AIG.
