Abstract

Abnormalities in the process of uterine muscle contractility during pregnancy and birth can have major clinical implications, including preterm labour, which is the single largest cause of maternal and prenatal mortality in the Western world and a major contributor to childhood developmental problems. In contrast, induction of labour may be necessary in certain conditions. Currently used interventional therapies to suppress (tocolytic agents) or to induce (uterotonic agents) uterine contractions lack potency and/or selectivity and can have harmful side effects for mother and baby. Nature’s diversity has always been, and still is, one of the biggest resources of therapeutic lead compounds. Many natural products exhibit biological activity against unrelated targets, thus providing researchers with starting points for drug development. In this review we will provide an overview of uterine muscle physiology, describe currently available biological screening procedures for testing of uterotonic plant compounds and will summarise traditionally-used uterotonic plants, their active components and their mechanisms, primarily focusing on uterotonic active circular plant peptides called cyclotides. Finally we will comment on the discovery of novel cyclotide-producing plant species and the possibility for the development of novel plant-derived uterotonic and tocolytic drugs.

Abbreviations

AC: adenylyl cyclase
CCK: cyclic cystine knot
COX-2: cyclooxygenase-2
CRH: corticotropin-releasing hormone
GPCR: G-protein coupled receptor
IL: interleukin
IP_3: D-myoinositol 1,4,5-triphosphate
MLC: myosin light chain
NF: nuclear factor
OT: oxytocin
PL: phospholipase
R: receptor
SFE: supercritical fluid extraction
SR: sarcoplasmic reticulum
TNF: tumour necrosis factor

Introduction

Traditional medicine relies on the use of certain herbal plants and other remedies for beneficial effects during pregnancy, to induce labour, in the removal of retained placenta and management of post-partum bleeding. However, some of these medicines have harmful side effects and when taken in large quantities can lead to the death of the unborn baby and/or uterine rupture, and other longer term effects on the mother or baby. Most often the biological effects elicited by these remedies are due to biomolecules (small chemicals, peptides or proteins) that primarily act on the uterus. The nature of these actions may involve the modulation of uterine contractions at labour, resulting in either the stimulation (“uterotonic”) or inhibition (“tocolytic”) of myometrial muscle contractions. In this review we will provide an overview of uterotic herbs and their active constituents. This includes traditionally-used as well as recently identified plants or isolated plant compounds, which have reportedly shown uterine smooth muscle-stimulating activities. Furthermore we will give a brief outline of available uterotonic assay systems and provide a list of uterotonic plants, their bioactive ingredients and their mechanism of action on the uterus. Our focus will be on the description of recently identified cyclotide peptides, mainly found in plants...
from the Rubiaceae and Violaceae families, which have shown to be uterotonic agents. We will begin this article with a thorough description of uterine physiology and molecular details of uterine smooth muscle contractility.

Uterine Muscle Physiology

Biology of the uterus

The uterus is the central organ of reproduction. It is a thick, pear-shaped, muscular organ approximately 7 cm long, and 4–5 cm wide at its widest point. It is divided functionally and morphologically into three sections, namely the cervix, the isthmus and the main body of the uterus (corpus uteri) [1]. The myometrium is the middle muscular layer that makes up the major proportion of the uterine body. Myometrial smooth muscle is arranged in undefined layers and contractile forces can occur in any direction enabling the uterus to assume virtually any shape. Through growth and stretch during pregnancy, the myometrium provides the protective environment for the developing foetus. Then with the onset of labour it contracts rhythmically to expel the foetus and placenta. Smooth muscle fibres are composed of spindle-shaped cells, each with one centrally located nucleus. Typically, they have a diameter of 2–10 µm and a length of several hundred µm [2]. Smooth muscle cells are embedded in an extracellular matrix composed principally of collagen fibres, which facilitate the transmission of contractile forces generated by individual cells. They are organised into sheets of closely opposed fibres, oriented at right angles to each other. These sheets form two distinct layers, the “longitudinal layer”, which consists of a network of bundles of smooth muscle cells generally oriented in the long axis of the organ, and the “circular layer”, in which the fibres are arranged concentrically around the longitudinal axis of the organ [3]. Contraction of the longitudinal layer causes the organ to dilate and shorten, whereas contraction of the circular layer causes the organ to elongate; thus alternating contraction and relaxation of these layers enables the uterus to expel its contents at birth [2].

Uterine muscle contractility

The onset of labour is facilitated by phasic myometrical contractions that are driven by the development of action potentials across the plasma membrane, resulting from a transient increase in the cytosolic free Ca^{2+} concentration [4]. In this case (calcium-dependent smooth muscle contraction), calcium is released from the sarcoplasmic reticulum (SR) and from extracellular stores through voltage-gated calcium channels. Therefore smooth muscle contractility by different agonists or by electrical depolarisation results in a rapid increase in [Ca^{2+}]_i [5]. Ca^{2+} binds to four binding sites of calmodulin causing a conformational change allowing the calmodulin–calcium complex to interact with inactive myosin light chain kinase (MLCK), thus activating its enzymatic properties [6]. MLCK rapidly phosphorylates the 20 kDa myosin light chain (MLC). Phosphorylation of MLC leads to conformational changes in the myosin head that causes actin activation of myosin ATPase, resulting in force generation and/or shortening (contraction) of the muscle fibres [7]. Dephosphorylation of MLC by MLCK phosphatase (MLCP) results in smooth muscle relaxation [8]. Myometrial contraction is influenced by a variety of physiological mechanisms involving intracellular signalling, calcium, ion channels, cell membrane receptors, peptides, metabolic and neuronal factors and hormones [9]. The most important factors are described below and are summarised in Fig. 1.

G-proteins and G-protein coupled receptors involved in myometrial contraction

G-protein coupled receptor (GPCR) activation can result in profound stimulatory or inhibitory effects on myometrial contraction. For example, receptors coupled to G_{α_s}, e.g., oxytocin (OT) receptors, endothelin receptors, prostaglandin (PG) receptors E (subtype EP1), F (FP) and thromboxane A1 receptor, stimulate contractility by activating the phospholipase C (PLC)–Ca^{2+} pathway; receptors coupled to G_{αq}, e.g., a2-adrenoceptors as well as PG receptors DP, EP2 and IP relax the uterus by stimulating adenyl cyclase (AC) and increase myometrial cAMP levels; while
receptors coupled to Gαq, e.g., α2-adrenoceptors, muscarinic receptors, potentiate contractility by inhibiting cAMP production [10]. Activated G-protein subunits trigger many effectors, which can then regulate ion channel activity [11]—directly or indirectly, by stimulating/inhibiting phosphorylation pathways, initiating intracellular cascades leading to elevation of cytosolic Ca2+ or cAMP, or by generating various lipid-derived compounds that can alter channel activity [12]. K+, KATP and Maxi-K channels are all potential targets for direct regulation by GPCRs or the second messengers generated by GPCR-linked pathways [9, 10, 12].

In the following paragraphs we will provide more detail on the myometrial effects of OT, PGs and corticotrophin releasing hormone (CRH).

**Oxytocin:** OT is a potent uterotonic nonapeptide hormone [13], which is known to act both directly and indirectly to stimulate uterine smooth muscle contraction and is widely used for the artificial induction of labour [14]. It circulates as a free peptide in the bloodstream and, as with all hypothalamic hormones, is released discontinuously in a pulsatile fashion [15]. Its release into the bloodstream can be stimulated by the administration of PGs [16] or dopamine [17]. OT mediates most of its effects through the OT receptor (OTR), which is a member of the OT/vasopressin GPCR family [18] of the Gαq subfamily, to stimulate PLC activity [19]. OT induces contraction by elevating intracellular calcium concentration ([Ca2+]i), first by PLC-mediated 1,4,5-triphosphate (IP3) induced release of Ca2+ from internal stores [20–22], followed by influx of extracellular Ca2+ via voltage- and receptor-operated calcium channels [20, 23] or capacitative calcium entry [24]. OT also stimulates an increase in cytoplasmic phospholipase A2 (PLA2) activity and induces cyclooxygenase-2 (COX-2), the two major enzymes of PG biosynthesis [25]. OTR mRNA expression is influenced by several factors, including hormones, certain cytokines and transcription factors [18].

**Prostaglandins:** PGs are members of the eicosanoid family of proteins. They are lipid mediators produced by the uterus, foetal membranes and the placenta and are capable of modulating uterine contractions [26] and have been used in pregnancy for a variety of treatments [27]. When PG receptors are bound by their specific ligand, distinct intracellular pathways are activated, linked to the contractile (EP1, EP3, FP, thromboxane) or the relaxant (EP2, EP4, IP, DP) receptor isoforms [28]. PGE2 and PGF2α play important roles in myometrial contraction, cervical ripening and the initiation of parturition in humans [29]. The contractile effect of PGs is based on their ability to mobilise calcium and inhibit AC activity. PGE1 and PGF2α stimulate Ca2+ release from the SR of the myometrial cells [30]. PGs exert their effects through a number of GPCRs [31]. Binding of PGF2α to its contractile receptor stimulates G-protein (Gα11) activation of PLC and PLA2, which stimulate production of IP3 and intracellular calcium release [32, 33]. The released IP3 mobilises [Ca2+]i from the SR, resulting in increased uterine contractility. PGE2 exerts a dose-dependent increase in [Ca2+]i, mediated through Gαq [34]. The effects of PGE2 and PGF2α are mediated mainly through EP and FP receptor subtypes, respectively [35]. PGs have both direct and indirect effects on myometrial contractions, further increase uterine sensitivity to uterotonic agents, synchronise myometrial contractions [36, 37] and alter hormone synthesis [38]. Additionally, PG receptors EP2 and EP4 are responsible for smooth muscle relaxation and uterine quiescence [28].

**Corticotropin-releasing hormone:** CRH is a 41 amino acid polypeptide which mainly functions as the hypothalamic regulator of the mammalian stress response. CRH stimulates adrenocorticotropic hormone release from the anterior pituitary gland and consequently cortisol secretion from the foetal adrenal gland [39]. CRH action is mediated by multiple receptor subtypes with differential patterns of expression depending on the state of the myometrium (non-pregnant or pregnant – term/preterm) [40]. During most of pregnancy CRH, acting via CRH receptor subtypes coupled to AC, plays a “protective” role by promoting myometrial quiescence via generation of cAMP and cGMP, and upregulation of nitric oxide synthase expression [41]. CRH may also prevent contractions by inhibiting production of PGE2 [42]. During the third trimester, CRH derived from the placenta is secreted into the maternal circulation in large amounts [40]. At term, myometrial contractility is enhanced by a complex series of molecular switches, involving the upregulation of OTR expression and cross-talk between the OT and CRH receptors [43]. OT action is mediated via pertussis toxin-sensitive G-proteins, which directly inhibit AC and via activation of protein kinase C, phospholipase specific CRH receptor subtypes, leading to desensitisation [42]. Thus, CRH receptor binding affinity for CRH is lowered, causing a reduction in intracellular CAM levels, which results in a shift in the intracellular microenvironment in favour of contractility [41]. The function of CRH at term now changes, as it is able to enhance the contractile response of the myometrium, via distinct lower-affinity CRH receptor subtypes, through stimulation of prostannglandin PGF2α and PGE2 production [44]. CRH also stimulates placental release of OT [39]. Another function of CRH at term is the stimulation of cortisol and the production of dehydroepiandrosteredione, the precursor to oestradiol from the foetal adrenal gland [45].

**Steroid hormones involved in myometrial contraction**

**Oestrogens:** Oestrogens comprise a group of steroid hormones, including oestradiol, oestril and oestrone. They are synthesised mainly in the ovaries, although small amounts are also produced in the adrenal cortex and the placenta. During pregnancy oestrogens are responsible for uterine growth which ceases at the end of pregnancy, the consequent decreasing stretch of the uterine wall stimulates contraction [46]. In human nonpregnant myometrium, the inhibitory action of oestrogens is achieved through inhibition of receptor-operated calcium channels and possibly also the release of intracellular calcium [47]. Oestrogen is also linked to an increase in PLC isoform expression in uterine smooth muscle [48] and has been shown to up-regulate OTR concentration in myometrial cells [49]. Most, if not all, of the actions of oestrogens are mediated by interaction with the specific nuclear receptors, ERα and ERβ [50, 51].

**Progesterone:** Progesterone is another steroid hormone, primarily produced by the corpus luteum of the ovary, but also by the placenta that prepares the lining of the uterus for implantation of a fertilised ovum and maintains this state during pregnancy [52]. It is a pro-pregnancy hormone and negatively regulates many of the labour associated proteins. It supports uterine quiescence by stimulating a variety of relaxant mechanisms, such as the nitric oxide system, by suppressing myometrial responsiveness to uterotonic agents, primarily by inhibiting gap junctions [53]. It functionally opposes oestrogen action. In humans a functional withdrawal of progesterone precedes labour onset, the switch from the growth phase of pregnancy to the uterine stretch observed at the end of pregnancy due to pressure on the uterine wall from the foetus appears to be regulated by progesterone. Progesterone withdrawal increases the attachment of myocytes...
Inflammatory signals in labour and myometrial contraction

Many of the biochemical events involved in parturition resemble an inflammatory reaction, with growing evidence pointing to a crucial role for pro-inflammatory cytokines and PGs in labour [55]. This may in part be due to increased surfactant protein production in the foetal lung. Firstly, cortisol production in the foetal adrenal glands increases due to increased placental CRH production [56]. This results in foetal lung maturation with an increase in surfactant proteins which are critical for lung function. The surfactant proteins enter the amniotic fluid where they have macrophage activating properties [46,57]. In the mouse, surfactant protein A activates amniotic fluid macrophages, and these cells play an active role in labour onset [58]. In humans it is postulated that the surfactant proteins may stimulate the inflammation observed in the foetal membranes, cervix and myometrium at the time of labour [46]. Parturition is characterised by an influx of inflammatory cells into the maternal tissues, placenta and foetal membranes [59,60] and increased expression of pro-inflammatory cytokines in both preterm and term labour. Elevated levels of interleukin (IL)-1β, IL-6 and tumour necrosis factor TNFα are detected in amniotic fluid [61,62], myometrium and chorioidecidua [59,63] and cervicovaginal secretions [64]. These pro-inflammatory cytokines are thought to contribute to labour onset by stimulating the production of IL-8 and PGs. IL-8 acts in the formation of the lower uterine segment in late pregnancy and in mediating the inflammatory infiltrate seen in myometrium during labour [55]. IL-8 expression is induced by IL-1β, TNFα, lipopolysaccharide and phorbol esters. It has promoter binding sites for nuclear factor NF-κB, AP-1 and C/EBP [65]. PGs, in turn, cause cervical ripening and foetal membrane remodelling [66]. Both term and preterm labour are also associated with NF-κB activation [58], which, in turn, increases expression of genes promoting myometrial contractility, including the PGF2α receptor [66], the gap junction protein connexin 43 [67], the OTR [68] and COX-2 [69]. Following the description of myometrial signalling and uterine contractility pathways, we will provide and overview of uterotonic test systems.

Biological Screening Assays for Uterotonic Agents

Suitable models are essential to study the processes involved in myometrial contraction and the agents which mediate these responses. The use of in vivo studies is not ideal as the process of labour differs amongst animals, and human parturition is distinct from that of other mammals, which limits the use of animal models [70]. Isolated organ bath assays are the classical pharmacological screening tool for isometric recordings to assess concentration-response relationships in contractile tissue (for overview see [71]). The organ bath assay permits complex responses to be studied where tissue responses are controlled by several physiological parameters. Myometrial tissue strips have been used for tissue bath experiments, but ethical constraints and difficulties in obtaining human samples limit the use of this system. Alternatively, electrophysiology studies using the well known patch-clamp technique can be conducted to measure responsiveness of contractile tissue. The patch-clamp technique is a method to study the electrophysiological properties of biological membranes (for overview see [72]). In addition to these classical pharmacological and electrophysiological assays, there are two recently developed techniques to study the biological effects of uterotonic agents, which will be described in the following sections.

Supercritical fluid extraction coupled online to uterotonic assays

Supercritical fluid extraction (SFE) is the process of separating components from solid or liquid matrices using supercritical fluids as extracting solvent. The technique’s origin is as a large-scale process used in the food and pharmaceutical industry and for environmental analysis [73,74]. It is used to purify required compounds from mixtures, such as the collection of essential oils from plants, or to extract unwanted compounds or contaminants from a product. More frequently it is being used as a sample preparation and analytical method for the extraction of various natural products [73].

A modified and optimised SFE method has been used by Sewram and colleagues to extract and analyse several plants for their uterotonic activity [75,76]. The SFE extracted plant fractions are coupled online to the uterotonic bioassay, i.e., isolated uterine muscle strips (guinea pig) that are placed in an organ bath chamber, which is connected to the extraction chamber. This method also allowed the pretreatment of muscle contracting stimulants (e.g., acetylcholine or bradykinin) or blockers (e.g., HOE 140 or atropine) to further analyse possible mechanisms of uterine contractility [76]. The described approach has been validated by testing aqueous extracts of Clivia miniata (Lindl.) Regel [75]. This plant has shown comparable uterotic activity in an independent study using an isolated organ bath [77]. Although the uterotic bioassay used in this set-up is different from that described previously (organ bath methodology), the SFE coupled online to uterotonic assays offers the advantages of reduced extraction time, increased sensitivity, easier analyte fractionation and enhanced reproducibility due to protection of environmental influences of the extraction procedure and bioassay measurements [76].

Collagen contractility assay

Collagen is an ideal substrate for uterotonic assays as it forms the main component of the extracellular matrix in vivo and it does not cause cytotoxicity. Bell et al. described the formation of a “tissue-like structure” produced by seeding fibroblasts in a collagen matrix and collagen lattices are now widely used as in vitro models for many diverse purposes [78]. Furthermore, preparation of lattices can be altered to best mimic the tissue of interest. Using an isolated cell system allows the study of effects on cells by individual stimuli, without interference from other sources. Type 1 collagen is widely available, so studies are not restricted by sample number. With tissue strip experiments, inherent differences exist between myometrial samples; however, with this collagen contractility system a uniform solution of cells and collagen is used, ensuring that all replicates are comparable. Examples of the utilisation of the collagen contractility assay on uterine cells include: (i) the monitoring of the effects of endothelin-1 on human myometrially-derived smooth muscle cells [79], (ii) determination of the effect of OT and its inhibitors on two human myometrial cell lines, i.e., telomerase-immortalised human myometrial cells (hTERT-C3) and a cell line derived from primary culture.
of human myometrial cells [80], (iii) study on primary human uterine smooth muscle cells (hUTSMCs) that demonstrated increases in gel contraction with OT, KCl and TNFa [81] and (iv) the modulation of primary hUTSMC and hTERT-HM myometrial smooth muscle cell contractility by thrombin, the ROCK inhibitor Y-27632, TNFa and the prostaglandin inhibitor indomethacin [82–84]. Therefore, the collagen contractility assay is an effective and robust in vitro model of human myometrium [79,80,82–84] (Fig. 2).

In particular, the assay allows the determination of the biological effects of various unknown (plant) compounds on uterine smooth muscle contractility. To determine the biochemical pathways involved in the modulation of myometrial contractility some clinically used inhibitors may be applied to the assay, such as indomethacin (a non-selective PG receptor inhibitor), COX-2 inhibitors, atosiban (OTR inhibitor), nifedipine (calcium channel blocker), ritodrine and terbutaline (β2-adrenergic receptor agonists), salbutamol (β2-sympathomimetics) and Y-27632 (Rho kinase inhibitor). Furthermore, this contractility assay set-up allows investigations at the molecular biology level by isolating RNA and protein from the cells in the collagen matrix, which has been previously demonstrated [82]. RT-PCR and Western blotting techniques may be utilised to monitor gene and protein expression changes.

Having presented a thorough description of uterine physiology, the molecular mechanisms of myometrial muscle contractility and currently available uterine contractility assay systems, we will now provide an overview of traditionally-used and recently identified uterotonic plants and their bioactive constituents.

Uterotonic Plants and their Bioactive Constituents

The use of herbal medicine to alleviate problems associated with gynaecological conditions of menstruation and menopause, to support health during pregnancy and to facilitate childbirth is common amongst many traditional cultures. Detailed ethnobotanical surveys have been reported for several native communities around the world and many traditionally-used plants or remedies have been identified.

Traditionally used plants in gynaecology

Traditional cultures rely on the beneficial effects of herbal remedies during pregnancy, birth and post-partum care. The knowledge and the correct use of these natural medicines has been acquired and improved over many generations. Documentation of traditional knowledge of medicinal plants is crucial, since it provides chemists and pharmacologists with starting points for “targeted” analysis, discovery of novel remedies and natural drugs for the treatment of pregnancy and birth-related problems. Ethnobotanical studies with the aim to identify and document the native use of plants to treat gynaecological health issues have been reported, e.g., for Argentina [85], China [86,87], Dominican Republic [88], Honduras [89], Indonesia [90], Laos [91], Mexico [92], Tonga [93], Vanuatu [94], Thailand [95] and many others. Some studies provide initial pharmacological characterisation, e.g., preliminary biological testing of uterotonic effects of 28 plants from Ethiopia [96], identification of active compounds of 12 plant species from Guatemala that bind to oestrogen and/or serotonin receptors [97] and identification of at least five uterotonic plant species from South Africa (see below) [98].

The use of plant remedies is also documented in native Northern America, where herbal medicines are taken as tonics during pregnancy to prepare for labour (e.g., raspberry leaf, partridge berry and stinging nettle), to prevent miscarriage (e.g., black cohosh and beth root) [99]. Preparations of black cohosh root (Actaea racemosa [Nutt.] L.), Goldenseal root (Hydrastis canadensis L.) and Chaste tree fruits (Vitex agnus-castus L.) are listed in the U.S. Pharmacopoeia and are available as dietary supplements to be used for premenstrual stress syndrome, as emmenagogue agents and for gynaecological problems. Other traditionally used medicines, such as raspberry leaves (Rubus idaeus L.) [100], castor oil (Ricinus communis L.) [101] and cotton bark root (Gossypium hirsutum L.) [102] are again receiving attention from midwives for applications during pregnancy and labour [103,104].

Infusions of various plant species have been used from early times to treat ailments of pregnant women in traditional medicine of central European countries, e.g., Austrian traditional medicine [105] as well as in some countries of the Balkans, e.g., Bosnian traditional medicine [106]. For example, German chamomile (Matricaria recutita L.), small-leaved lime (Tilia cordata Mill.), and large-leaved lime (Tilia platyphyllos Scop.) as well as aerial parts of marjoram (Origanum majorana L.) and fruits of caraway (Carum carvi L.) have been used to ease the birthing process.
Uterotonic active plants

There is a vast array of information available on traditionally used herbs to treat gynaecological problems. The medicinal properties of many of these plants have not yet been studied in molecular detail but it is clear that they may affect a number of different physiological targets and pathways in the female body. The focus of this review is on uterotonic plants and we will briefly provide the selection criteria of plants listed and described in this article. There are at least four categories of medicinal plants (and their active constituents) that exhibit activity on the uterus:

1. Symptomatic/traditional categorisation: Plants used for the treatment of menstruation problems – dysmenorrhoea (= severe uterus pain during menstruation) or menopause symptoms, herbal medicines with oxytocic or emmenagogue properties (= herbs that stimulate blood flow in the pelvic area and uterus) used during childbirth and pregnancy and herbal medicines with abortive properties.

2. Biological categorisation: Uterine-stimulating plants (uterotonic) and uterine-inhibiting plants (tocolytic).

3. Pharmacological categorisation: Agonists or antagonists (full, partial, inverse) of uterine contractility-related pathways.

4. Chemical categorisation: Small chemical compounds, peptides or proteins.

We have included plants, plant extracts or pure plant-derived compounds that have demonstrated the stimulation of uterine contractility (uterotonic) in vivo or in vitro. Plants that indirectly elicit effects on the uterus, such as the increased production of uterotonic substances (e.g., observed upon the administration of *Artemisia monosperma* in rats [107]) or the upregulation of PG synthesis, have specifically not been included. We have also not included substances that inhibit uterine contractility (tocolytic agents). Furthermore, any pure plant-derived uterotonic compounds that are already marketed drugs (or in clinical trials) as stimulants of uterine contractility, have not been included. Following these criteria, we have surveyed the literature for uterotonic plants and active plant compounds, which are listed in Table 1.

Uterotonic plant compounds: the discovery and application of cyclotides

Upon compilation of the comprehensive list of uterotonic plants, we will describe uterotonic plant constituents, with an emphasis on the characteristics of the active compounds and their molecular mechanisms. Of particular interest is a class of circular plant peptides, so-called cyclotides, which have recently attracted much attention due to their pharmaceutical and agro-chemical applications.

We have identified and summarised (Table 1) at least 40 plant species, which appear to have pharmacological evidence for uterotonic activity. It is clear that there are many more uterotonic plants to be discovered, but they have either not yet been tested or do not appear as “uterotonic” in the literature. Although the majority of the plants listed here have been studied thoroughly for their biological activity, their active component(s) or the active principle(s) are not yet fully understood. Examples of isolated and identified uterotonic plant compounds include diterpenes (kaurenoic acid, grandifloric acid and kauradienoic acid; isolated from *Montana tomentosa* and *Aspilia mossambicensis* [108–110]), phenylpropanoid glucosides (Z-venusol; *Gunniera perpensa*), [111], heterocyclic aldehydes and fatty acids (5-hydroxymethylfurfural and linoleic acid; *Clivia miniata*), [75, 77], steroidal saponins (penogenin glycosides; *Paris polyphylia* [112], plant sterols (β-sitosterol; *Punica granatum*) [113] (Fig. 3), and circular polypeptides, so-called cyclotides.

The discovery of the first cyclotide, kalata B1, from the coffee family (Rubiaceae) species *Oldenlandia affinis* was due to its use in African traditional medicine to accelerate childbirth by uterine stimulation [114, 115]. Cyclotides are disulfide-rich plant peptides [116] of about 30 amino acids in size and possess the unique structural features of a head-to-tail cyclised backbone and a knotted arrangement of three-disulfide bonds, referred to as a cyclic cystine knot (CCK) motif [116] (Fig. 4). The compact CCK motif makes cyclotides exceptionally resistant to thermal, chemical or enzymatic degradation [117]. In contrast to secondary plant metabolites, cyclotides are true gene products. Their biosynthesis starts from larger precursor proteins and reportedly involves enzymatic processing [118, 119] as well as protein folding events [120].

Lorents Gran studied the pharmacological properties of kalata B1 and found that the peptide induced OT-like uterine muscle contractions in vitro with isolated rat and rabbit uteri and human uterine strips at concentrations of 10–20 µg/ml [115] and this has been confirmed by Gran and colleagues, which reported the uterotonic activity of kalata B1, B2 and B7 at concentrations of 0.5–20 µg/ml [121]. Similar effects were observed in vivo (rat and rabbit) upon peritoneal administration of ~20 µg/kg kalata B1 solution. However, intravenous injections of doses of ~1 mg/kg were found to be toxic (increased blood pressure and ventricular tachycardia) and eventually lethal (ventricular fibrillation) [115]. It is intriguing to further explore the uterotonic effect of cyclotides in molecular detail, in particular because kalata B1 [122], and other cyclotides (for instance tricyclons A and B from the violet plant *Viola tricolor* L. [123]), contain sequence and/or structural motifs that are similar to the presumed activity-bearing motifs in the OT peptide [124, 125]. Aside from their uterotonic activity, cyclotides also exhibit a range of other biological functions, including haemolytic [126], anti-neurotensin [127], anti-HIV [128] cytototoxic [129], anti-bacterial [130], anti-fouling [131] and nematocidal [132]. One of their main natural roles

¹ Active compounds have not yet been identified. ² These compounds are also found in Montanoa tomentosa. ³ Formerly known as Escovaria bicolor Zoll. Ex. Hask. ⁴ Pharmacological evidence not clear, since the extract also showed relaxing activity on skeletal and ileum smooth muscle. ⁵ Other species of the genus Luffa, e.g., L. chinensis also show what has been reported to be uterotonic activity [192]. ⁶ T. cyclindrica contains ribosome-inactivating proteins, that are thought to be responsible for its abortifacient activity in mice [193]. ⁷ Active compound is possibly a small peptide with the sequence YLS. ⁸ Other Montanoa spp. (i.e., M. frutescens, M. hibiscifolia) report uterotonic and spasmolytic activities. ⁹ Other species from Violaceae and Rubiaceae do contain cyclotides, potentially with uterotonic activity.

Concluding Remarks

…to the discovery of new cyclotides, the search for novel uterotonic plant species and the analysis of their structural and functional properties becomes even more important. The identification of new cyclotides and related peptides promises to expand our understanding of their biological activities and to provide new leads for drug development.

Recombinant expression of cyclotides in plants provides a unique opportunity to study their biological functions in vivo and to develop new treatments for various diseases.

References

and gynaecological health-care, but have not yet been pharmacologically tested for uterotonically active, such as *Cephaelis tomentosa* (Aubl.) Vahl. [97], *Pentanisia prunelloides* (Eckl.+Zeyh.) Walp. [98], *Rondeletia stachyoides* Donn. Smith [97], *Spermacoce princeae* (K. Schum.) Verdc. [153], *Vangueria apiculata* K. Schum. [153] (all Rubiaceae), *Akoka* *therapeutica* K. Schum. [96], *Calotropis procera* (Ait.) Dryand. [96] and *Rauvolfia caffra* Sond. [98] (all Apocynaceae).

Both the taxonomy-guided and the activity-guided discovery approaches may lead to finding novel cyclotide-producing plant species, which will not only help to understand their diversity and evolution, but also provide novel molecules for biological testing and potentially new entities for drug development of uterotonic as well as tocolytic agents.

**Importance of uterine active agents for clinical use**

During pregnancy the uterus undergoes dramatic changes in its contractile activity, going from a state of quiescence to one of maximal contractile activity at labour. The initiation of labour is a complex physiological process that requires the expression and secretion of many maternal and foetal factors that exert their effect on the myometrium, the uterine smooth muscle responsible for expelling the foetus from the uterus in strong synchronous contractions. Abnormalities of this process have major clinical implications, including preterm labour, the single largest cause of maternal and perinatal mortality in developed countries and a major contributor to childhood developmental problems [154, 155]. An estimated 28% of the 4 million annual neonatal deaths are due to preterm birth and approximately 12.9 million babies are born prematurely every year, which estimates to a global prevalence of preterm birth of 9.6% [156, 157]. This results in huge costs to healthcare systems internationally. Figures from 2005 from the USA indicate that the annual societal economic cost (medical, educational, and lost productivity) associated with preterm birth from birth through early childhood was at least US$ 26.2 billion [158].

Currently used intervention therapies to suppress uterine contractions and delay labour, have harmful side effects for mother and baby. There is both a clinical need and a commercial opportunity for the identification of novel therapeutic agents for preterm labour. Current, so-called tocolytic therapies to inhibit preterm labour remain targeted at modulating uterine contractions. The only FDA approved treatment for preterm labour is ritodrine, a β2-adrenergic receptor agonist. However, it was withdrawn in 1999, due to side effects. A more widely used treatment for preterm labour, terbutaline, is not approved by the FDA for preterm labour. Other tocolytics include magnesium sulphate and nifedipine. The usefulness of β2-adrenergic agonists is limited by the side effects they produce, including cardiovascular side effects, such as heart palpitations (via stimulation of β1-adrenergic receptors). The side effects of PG synthesis inhibitors are well known and include ulcers, asthma and cardiovascular problems. Atosiban, an OT antagonist is available in Europe, but was denied regulatory approval in the USA. Thus, there is a need for treatments that are effective in reducing the premature birth rate and/or providing for longer gestation, with better safety and tolerability profiles. The ideal tocolytic agent would be highly specific for uterine smooth muscle and would have minimal side effects for both mother and neonate.

In contrast, induction of labour may be necessary in certain conditions and is advocated in cases of post-term pregnancy, lack of progress, oligohydramnios, suspected intrauterine growth restriction, maternal cardiac disease, pre-eclampsia/ eclampsia, pre-labour rupture of membranes at term and foetal macrosomia [159]. Uterotonic or oxytocic drugs are used to induce or augment labour and in the prevention or treatment of post-partum bleeding [160]. OT is used for labour induction and associated complications during the third stage of labour include post-partum haemorrhage, retained placenta and uterine inversion [161]. Furthermore, PGs are used to induce labour and to prevent or treat post-partum haemorrhage [162], while synthetic ergot alkaloids cause strong titanic contraction of the uterus.

In summary, there is a great need for potent, selective and non-toxic therapeutic agents (agonists and antagonists) for recep-
tors/signalling pathways that regulate uterine muscle action. Traditionally used herbal medicines and their active ingredients, such as cyclotides found in flowering plants, are ideal starting points for biological target-oriented drug discovery efforts. The search for novel cyclotide-producing plants and their pharmacological characterisation may eventually lead to the development of novel uterotonic or tocolytic drugs.
