Introduction

Medulloblastoma is the most common central nervous system tumor in children,¹⁻³ and accounts for ~22% of the malignant tumors in the pediatric population.⁴⁻⁵ In the United States, the incidence of this neoplasia is 0.6 per 100,000 patients no more than 14 years old, and accounts for 17% of all brain tumors in this group. There appears to be a bimodal age distribution in children, with peaks at ages 3 to 4 years and at ages 8 to 9 years.¹ Extra-axial medulloblastomas, especially tumors with no connection to the brain stem or cerebellum are extremely rare.²⁻⁶ Patients with medulloblastomas usually present with nonspecific clinical signs, often being confused with other tumors that show similar symptoms and imaging exams.³ Therefore, we emphasize through this case report, the
importance of the differential diagnosis of this tumor, when approaching neoplasms located in the posterior fossa, as well as its therapeutic principles.

Case Report

A 3-year and 11 month-old female patient was taken to the hospital, with a history of subacute headache, which was initially related to sinusitis. She had no previous history of tumor, neither any other disease. Later, the patient developed episodes of vomiting, and a computerized tomography scan was indicated, despite her neurological exam, that was normal. The presence of a mass, located in the posterior fossa, in the left cerebello-pontine angle, was detected, along with concomitant hydrocephalus (Fig. 1–3). After resolution of intracranial hypertension, with dexamethasone, the patient underwent microsurgical excision of the tumor. The approach was through a left retrosigmoid suboccipital access, identifying a soft, friable, well-defined mass, with a clear arachnoid plane, separating the tumor from the cerebellum, allowing its complete excision. The anatomopathological examination of the lesion confirmed the diagnosis of desmoplastic medulloblastoma (Fig. 4). The patient evolved with good clinical conditions in early and late postoperative care, in a 12 months follow up, with brain and spine radiologic exams and cerebrospinal fluid (CSF) cytology results negative for any signs of remnant tumor or metastasis (Figs. 5–7).

Discussion

Medulloblastoma is a tumor that affects predominantly the pediatric population. It's a poorly demarcated, pink-purple, soft friable mass, which arises from the cerebellar vermis, usually from the inferior medullary velum. There may be foci of hemorrhage or necrosis, but cysts are unusual. Desmoplastic variants may be more firm, as a result of their greater connective tissue component. In the

early stages of the central nervous system development, the cerebellar progenitor cells arise from two major germinal zones, and generate distinct populations of the neural cells that compose the cerebellum: the peri-ventricular germinal matrix, in the cerebellar plate, over the fourth ventricle, and the external granular layer. As this tumor has a neuroectodermal origin, its extra-axial location may be associated to remnants of the neural crest stem cells, which persisted specifically in the cerebello-pontine angle, from where the medulloblastoma arose. The tumor may extend through the fourth ventricle into the aqueduct of Sylvius or into the cisterna magna, through the foramen of Magendie. Involvement of the cerebellar hemispheres is uncommon in children, but more frequent in adults. Brainstem infiltration is seen in 15 to 40% of cases. Medulloblastoma has a strong propensity to metastasize, and the most common site for metastasis is the subarachnoid space. There are few cases of medulloblastoma located in the cerebello-pontine angle, with extra-axial location, and this phenomenon is extremely rare.

Most children present with the classic triad of morning headache, vomiting and lethargy, but these symptoms are nonspecific. Cerebellar signs, such as truncal ataxia, limb

ataxia, or dysmetria may also occur. Brainstem invasion is suspected if there are bulbar or facial palsies, although sixth nerve palsy is usually a result of hydrocephalus. It is very important to pay attention to the differential diagnosis of tumors located in the posterior fossa, specifically in the cerebello-pontine angle, including: vestibular neuroma, facial nerve schwannoma, meningioma, primary cholesteatoma, and epidermoid tumors, among others. In magnetic resonance imaging (MRI) exams, the medulloblastoma is usually hypointense to gray matter on T1, shows enhancement by Gadolinium, and may be iso- or hyperintense to gray matter on T2. Vestibular neuromas usually show intermediate signal intensity on T1 weighted images, increased intensity in contrast enhanced T1, and may not be seen in T2; facial nerve schwannoma images are identical to vestibular neuromas in MRI, showing a middle cranial fossa mass, which extends from the internal acoustic canal to the geniculate ganglion; meningiomas are related to increased vascularity, and hypointensity on MRI, when compared with these other tumors; primary cholesteatomas are hypointense in T1 and hyperintense in T2, similar to the cerebrospinal fluid; epidermoid tumors are best seen on T2 weighted images, with different levels of signal intensity, according to the keratin, cholesterol or water content of the tumor. Involvement of the V, VI, VII, VIII, and lower cranial nerves, and signs of cerebellar dysfunction are commonly noted in CP angle lesions. The early onset of signs of cerebellar ataxia may indicate an axial origin of the tumor, while positional nistagmus may be suggestive of acoustic schwannoma.

The goals of surgery are to establish a histologic diagnosis, maximally resect the tumor mass, and promote resolution of hydrocephalus. Postoperative radiation and chemotherapy are used to eliminate residual disease. The patients’ follow-up is done using brain and spine magnetic resonance imaging and CSF cytology, searching for metastasis or residual disease.

Conclusion

Despite the fact that extra-axial medulloblastomas are extremely rare, this differential diagnosis should be included in the management of patients who present with posterior fossa tumors, especially in the CP angle. Clinical and radiological exams not often give the definitive diagnosis of the disease. Therefore, this report is of importance to the neurosurgeon, especially in managing the diagnosis on children.
