Abstract

Intramedullary spinal cord abscess is a rare infection of the spinal cord with less than 120 cases reported since its first description by Hart in 1830. It is usually associated with abnormalities of the spinal cord or documented source of infection or immunodeficiency, requiring clinical radiological suspicion for accurate diagnosis. The first case is a middle-aged healthy woman without any underlying risk factors, presented with progressive paraparesis, in whom prompt, accurate diagnosis with contrast magnetic resonance imaging, diffusion-weighted imaging, and apparent diffusion coefficient mapping followed by early surgery was possible, which resulted in the favorable neurological outcome. The second case is a 10-year-old boy with paraparesis whose definite treatment and surgery was delayed due to a delay in accurate clinical and radiological diagnosis which resulted in poor outcomes. Hence, we try to establish that prompt diagnosis and surgical treatment can result in a favorable neurological outcome, though the prognosis, in general, is poor in this clinical condition. A review of literature in support of our cases is given.

Background

Intramedullary spinal cord abscess (ISCA) is a rare condition, especially in children. In children, developmental anomalies such as infected dermal sinus tract is a common source of ISCA whereas in adults, most cases are cryptogenic or hematogenous. Although uncommon, these infections are associated with significant mortality and morbidity, especially in the preantibiotic era. Clinical suspicion and radiological findings are essential for early diagnosis and treatment. Early diagnosis by contrast magnetic resonance imaging (MRI) and diffusion-weighted imaging (DWI) followed by surgical drainage and broad-spectrum antibiotics can significantly reduce the mortality. We suggest our cases as examples to prove this argument.

Cases and Review

Intramedullary spinal cord abscess (ISCA) is a rare infection of the spinal cord with fewer than 120 cases reported since

its first description by Hart in 1830.^{1,2} Traditionally these infections have been associated with significant mortality and morbidity.³ The first review of cases of ISCA described between 1830 and 1994 reported 90% mortality rate.⁴ Following the introduction of antibiotics into clinical practice, there is an apparent improvement in the outcomes of these infections. A recent review between 1994 and 1977 reported a mortality rate of only 8%.³ Kurita et al described a case of cervical ISCA treated by antibiotics alone but whether it is enough is a matter of debate.¹ ISCA is rare in children with only 38 cases reported in children.⁵

A case of ISCA is defined by a culture of a spinal cord aspirate yielding a bacterial pathogen, positive gram staining for bacteria or MRI suggestive of the features of abscess when the specimen is sterile or a positive immunology test for a specific bacteria.³

The majority of cases of cryptogenic ISCA are located in the cervical and upper thoracic segments of spinal cord, whereas in congenital midline defects lower thoracic and lumbar segments are the common sites. A review of the blood supply of the

spinal cord reveals and increase in both the number and caliber of vessels that perfuse these segments in comparison with the blood supply of the lower segments of the spinal cord.^{3,6} MRI features include increased signal intensity on the T2W image and marginal enhancement with central low signal intensity on the T1W image with gadolinium.⁷

In the first case of a 58-year-old female patient, MRI showed an intramedullary lesion with peripheral ring enhancement and mild enlargement of the cord at lower cervical and upper dorsal region (►Fig. 1a-d). The second case of a 10-year-old boy shows similar lesion at the lower cervical and upper dorsal region.

Fig. 1 The figure shows intramedullary lesion with peripheral ring enhancement: (a and c) sagittal contrast and (b and d) axial contrast.

The radiological technique of choice is an MRI with intravenous gadolinium to accurately determine the location and size of ISCA and to identify any predisposing structural abnormalities of the spinal cord or vertebral body.^{8,9} MRI features include increased signal intensity on the T2W image and marginal enhancement with central low-signal intensity on the T1W image with gadolinium.⁷ A ring-enhancing mass is a nonspecific finding and a variety of noninflammatory benign and the neoplastic process can have a similar appearance. The diagnosis of a ring-enhancing mass include primary and secondary spinal cord tumors (necrotic gliomas, metastases), resolving hematoma, infection, and demyelinating diseases.¹⁰

DWI has been added to the diagnostic imaging techniques in the recent years and it has been recommended as a more sensitive and specific method for distinguishing an abscess from cystic and necrotic spinal cord tumors.¹¹ Like brain abscess, the high-signal intensity of the abscess pus on a DWI scan that is associated with a low apparent diffusion coefficient can help to distinguish ISCA from cystic spinal tumors.¹² Murphy et al described that the chronological changes of MRI findings in the spinal cord reveal the same progression that has been documented in the brain (► Fig. 2a, b).^{13–15}

ISCA is a symptomatic infection of the central nervous system with histopathological features and stages of abscess development that are remarkably similar to those in the cases of the pyogenic abscess in the later stages of abscess development, the central core of pus is surrounded by a

well-vascularized capsule. The inflammatory process may extend to the meninges and cerebrospinal fluid space.²

A review of the literature by Kurita et al suggested that the clinical presentation of ISCA are the motor and sensory deficits in 68%, urinary incontinence in 56%, fever in 40%, meningism in 12%, and brain stem dysfunction in 4%. The triad of ISCA is fever, pain, and neurological deficits, but these do not occur in all patients.

Regarding our two cases, the first case was a 58-year-old female with no history of trauma, surgery, or significant comorbidities was referred to us with pain in the interscapular region, low-grade fever, and progressive weakness and spasticity of both lower limbs followed by upper limbs and retention of urine, all symptoms over a period of 2 weeks. Pain and temperature sensations were decreased below D4.

The second case was a 10-year-old boy with no history of significant infections or spinal abnormalities, referred to the neurosurgery department after 3 months of conservative treatment empirically with antituberculous drugs. When he was admitted to us, he had grade 0 power in both the lower limbs, no sensations below the chest, and bladder catheterized.

While the first one was an acute presentation and diagnosed early, the second case of the boy was referred very late to neurosurgery and hence definitive treatment was delayed. Radiological features were similar in both the cases.

The cause of infection is usually described as (1) contiguous spread from an adjacent source of infection, (2) direct inoculation, that is, penetrating trauma, postneurosurgery, (3) hematogenous spread from an extraspinal identified of infection, and (4) cryptogenic when no documented extraspinal source identified.³ In both our cases, a definite source of infection was not evident.

In the preantibiotic era, 50% of the cases were due to the hematogenous spread, whereas less than 10% of the cases in modern era result by hematogenous route.¹⁶ Tooth infection, pericolic abscess, and suppurated lung diseases are the common sources followed by soft tissue infections and infective endocarditis.^{1,3} In the present era around 25% of the cases are from contiguous spread of infection from dermal sinus tract. Congenital midline defects and anatomic abnormalities of the spinal cord or vertebral column are predisposing factors in pediatric ISCA through which infection occurs.¹⁷ The causative organisms in these cases include the microorganisms colonizing the skin surrounding the sinus tract openings.¹⁶ In the lumbar region, these pathogens involve gram-negative rods, anaerobes as well as *Staphylococcus* species. A series of experiments have demonstrated that metastatic abscess in the spinal cord results from an infection in the area of infarction or septic embolization.

The majority of recent cases are cryptogenic in origin. Transient bacteremia originating from mucosal infection or from the clinically unrecognized extraspinal source of infection resulting in the seeding of areas of subclinical spinal cord injury or microinfarction has been postulated as the cause of an abscess in these cases.³

Fig. 2 (a) DWI. (b) ADC. ADC, apparent diffusion coefficient; DWI, diffusion-weighted imaging.

Pulmonary A–V malformation may allow septic microemboli to enter the systemic circulation by escaping the normal pulmonary capillary filtering mechanism and cause abscess in the brain and ISCA.^{3,18} Transient bacteremia from odontogenic source is postulated as another cause of cryptogenic lesion in the brain and the same mechanism may be seen in ISCA.

Although 30% of the cases can be microbiologically sterile, various organisms have been isolated from ISCA including *Staphylococcus*, *Streptococcus pneumoniae*, *Haemophilus*, proteus, *Listeria*, *Actinomyces*, *Pseudomonas*, and *Mycobacterium tuberculosis*.¹⁹ Isolates from odontogenic source, includes *Viridans streptococci*, *Haemophilus*, and *Actinomyces* species.

Gupta et al reported a case of intramedullary tubercular abscess in a diagnosed case of Pott spine that failed to respond to antituberculous treatment and had to undergo surgery and drainage after 4 months.²⁰ The management of ISCA involves a combination of medical and surgical treatment similar to a pyogenic brain abscess.³ Once the diagnosis is made, surgical drainage regardless of the age is advocated by many authors to avoid a progressive neurological deficit by the space-occupying lesion.^{9,15,21,22} Prompt surgical evacuation through limited laminectomy and myelotomy with copious irrigation with normal saline followed by antibiotics, according to culture and sensitivity is the treatment of choice; any associated anomalies should be treated simultaneously.⁹

Kurita et al reported a case treated successfully by antibiotics alone¹ while Gupta et al reported a bad outcome in medical treatment alone and emphasize the need for early surgical drainage.²⁰ We did a limited laminectomy, myelotomy, and drainage of pus followed by irrigation with saline in both cases. The culture yielded *Staphylococcus aureus* in the first case while it was sterile in the second case (►Fig. 3).

The outcome of ISCA was poor in the preantibiotic era, but prompt diagnosis, early and adequate surgical treatment along with antibiotics can offer favorable outcomes. The outcome in our two cases was different. The first case which was diagnosed and treated promptly, improved neurologically and was able to walk with support after 3 to 4 weeks. After 4 months, she was

Fig. 3 Myelotomy: abscess cavity after drainage of puss.

free of the catheter. The second case was diagnosed very late and did not show any neurological recovery even after 6 months of follow-up. The comparison of our two cases clearly shows that early diagnosis and surgical evacuation along with broad-spectrum antibiotics can result in a favorable neurological outcome.^{9,23}

Conclusion

A high index of suspicion is needed for the diagnosis of ISCA in a patient with fever, backache, and rapidly progressive neurological deficit. Contrast MRI and DWI are helpful in accurate diagnosis. Timely surgical drainage and antibiotics can prevent irreversible spinal cord damage. Our cases clearly depict the need of prompt diagnosis and timely intervention in preventing permanent disability due to ISCA. In the first case, early diagnosis and emergency intervention saved the patient, whereas, in the second case, delay in diagnosis and surgical intervention led to permanent neurological damage.
