A spontaneous hemoperitoneum during the second or third trimester is a rare event that must be managed rapidly because of the potential risks to mother and fetus. At the same time, both its certain diagnosis and the identification of its cause are difficult. Hemoperitoneum in pregnant women appears in its most standard form as acute abdominal pain, sometimes accompanied by maternal shock, depending on its volume. Diagnosis during pregnancy is difficult because of its low prevalence and its nonspecific clinical findings; it is rarely mentioned initially as a differential diagnosis for acute abdominal pain. Diagnosis of the cause is also difficult because both obstetric and standard causes (vascular, hepatic, splenic, gynecologic, or hematologic) must be considered and because computed tomographic and magnetic resonance imaging are used less often during pregnancy. The speed of diagnosis and treatment is a key element in maternal and fetal outcomes.

Case Report

We report here the case of a 29-year-old woman, with no notable medical or surgical history, gravida 2, para 1, who had a normal pregnancy with a vaginal delivery at term in 2012. The pregnancy in 2014 was proceeding normally until 30 weeks of gestation, when she sought care for uterine contractions and moderate vaginal bleeding at a level 2A maternity unit, where the staff, suspecting preterm labor, rapidly began intravenous atosiban for tocolysis and transferred her to our level-3 facility. When she arrived at 11 AM, her blood pressure was 95/46 mm Hg, heart rate 100 bpm, and temperature 37.4°C. The urinary dipstick test did not reveal proteinuria. Uterine contractions stopped, and a digital cervical examination showed a posterior medium long cervix, soft, and open1 cm. No evidence of vaginal bleeding was seen during the speculum examination. On obstetric ultrasound, we observed a fetus normal for gestation age, with an estimated weight of 1,660 g, an anterior placenta inserted low and apparently normal on imaging, and a cervical length of 22 mm. The fetal heart rate was normal, hemoglobin 10.8 g/dL, and testing for infection negative. Specifi- cally, her leukocyte count was < 10 × 109/L, C-reactive protein < 5 mg/L, and the vaginal swab and cytobacteriologic examination of the urine were both negative. Threatened preterm delivery was diagnosed. Tocolysis by atosiban continued, and corticosteroid (betamethasone) therapy for fetal lung maturation began.

At 10 pm, the woman reported intense, diffuse abdominal pain. The uterus was soft, and the findings of the digital cervical examination were unchanged. The fetal heart rate was normal. Ultrasound showed good fetal activity but revealed an intrauterine hematoma measuring 59 × 66 × 109 mm, in a left lateral position relative to the placenta, associated with moderately abundant left intra-abdominal...
effusion. Hemoglobin was 8.3 g/dL, for a loss of 2.5 g/dL since admission. Monitoring of blood pressure, heart rate, and oxygen saturation continued in the delivery room, and fetal cardiotocography was continuously recorded. We controlled the pain with oral paracetamol and nefopam. At midnight, the mother remained hemodynamically stable; her abdomen and uterus were soft and painless. Ultrasound showed increased peritoneal effusion, now on both sides of the abdomen. Fetal activity and heart rate remained normal, and hemoglobin was stable at 8 g/dL. The patient remained under continuous monitoring in the delivery room.

At 08 AM the next morning, her blood pressure was stable at 130/80 mm Hg and her heart rate 120 bpm; fetal heart rate was normal, and hemoglobin remained stable at 8 g/dL. On ultrasound, fetal activity was good and the intrauterine hematoma stable, but the peritoneal effusion had increased further and was now estimated at more than a liter. Hypothesizing a uterine rupture, despite the absence of any uterine scar or any history of an intrauterine procedure, we decided to perform a cesarean delivery under general anesthesia. We used an infraumbilical midline laparotomy to allow exploration of the peritoneal cavity if the hemoperitoneum turned out to have a nonobstetric cause. A moderate hemoperitoneum was found. The uterus appeared purplish all over, with the typical appearance of a Couvelaire uterus (∼Fig. 1); it thus suggested placental abruption. No uterine rupture was observed. The hemoperitoneum was caused by backflow of intrauterine blood through the left intrauterine tube. We performed a segmental transverse incision of the uterus, which proved to be transplacental. This cesarean delivered a girl weighing 1,655 g (appropriate for gestational age), Apgar 3/6/9, pH 7.34; she was immediately transferred to the neonatal intensive care unit. The placenta was anterior and inserted low. The delivery of the placenta was accompanied by numerous clots. Laboratory tests for coagulation were normal during the stay and until delivery, except for fibrinogen, which fell to 1.6 g/L few hours before cesarean section. The mother received a transfusion of two units of packed red blood cells, 3 g of fibrinogen to keep its concentration > 2 g/L, and 2 g of tranexamic acid. The postoperative course was simple, and no signs of preeclampsia developed. Her hemoglobin rose to 10 g/dL and remained stable through her discharge on day 5. The infant’s course was also favorable, and she was discharged after 41 days.

The pathology examination of the placenta showed a retroplacental cup-shaped depression measuring 8 cm on its largest axis, which confirmed the diagnosis of placental abruption, associated with thrombosis of 20% of the chorionic plate vessels. Maternal immunological and thrombophilia testing was performed for etiologic purposes; results were normal.

**Discussion**

Placental abruption is a well-known obstetric accident and a life-threatening emergency. A report that the standard clinical triad combining vaginal bleeding, abdominal and pelvic pain, and uterine hypertonia is found in only approximately 10% of cases explains the diagnostic difficulties.

To our knowledge, hemoperitoneum has never been reported to be associated with placental abruption. The nonobstetric causes of hemoperitoneum during pregnancy include ruptures of the maternal umbilical vein, aneurysms of the splenic artery or vein, spontaneous rupture of the liver or spleen, and hematologic causes (coagulopathy). The causes of spontaneous hemoperitoneum during the second and third trimesters of pregnancy nonetheless seem to be predominantly obstetric. The most frequent of these obstetric causes is rupture of dilated uterine vessels (varices). The literature also includes cases involving rupture of a uterine artery aneurysm or an unscarred uterus, especially in women with endometriosis or placental abnormalities (such as placenta percreta).

In this case report, the context and clinical picture at admission did not suggest placental abruption. Only the ultrasound examination revealed the presence of an intrauterine hematoma, and nothing about its appearance suggested placental abruption. These features did not initially seem to the obstetric team adequate to justify emergency delivery of this very preterm fetus. The appearance of hemoperitoneum made the diagnosis still more difficult, for this clinical feature has never, to the best of our knowledge, been described in the literature in association with placental abruption. In view of the left anterolateral position of the placenta, very near the uterine tube, we supposed that the hemoperitoneum came from the progressive evacuation of...
blood from the hematoma in the abdominal cavity. This backflow may have prevented the complete detachment of the placenta and thus enabled the favorable outcome. If we had known that placental abruption could be associated with hemoperitoneum, we might have performed the cesarean delivery earlier. We estimate the delay in delivery at 12 to 24 hours.

The onset of hemoperitoneum during the second and third trimesters can reveal a voluminous placental abruption. This diagnosis must be considered among the obstetric causes of hemoperitoneum, especially when imaging also shows an intrauterine hematoma, to avoid a delay in diagnosis that could have major consequences on both fetal and maternal morbidity and mortality.
