Abstract

Idiopathic intracranial hypertension (IIH) is a disease characterized by an increase in intracranial pressure, without presence of parenchymal lesions or hydrocephalus that justify it. Over 90% of cases there is association with stenosis of the dural venous sinuses. It is characterized by headache, tinnitus, nausea, vomiting and visual disturbances. Initial treatment is clinical and when it fails there is indication of invasive procedures, among them shunts and fenestration of the optic nerve sheath. Angioplasty of dural venous sinuses, when indicated, has shown an alternative with better results and less complications. We report a case of a female patient, with 27 years old, diagnosed with IIH and bilateral transverse sinus stenosis, which was treated by bilateral stenting and total resolution of symptoms. Besides describing the case we review the literature about the subject.

Resumo

Hipertensão intracraniana idiopática (HII) é uma doença caracterizada pelo aumento da pressão intracraniana, sem a presença de lesões parenquimatosas ou hidrocefaíla que a justifiquem. Em > 90% dos casos, há relação com estenose de seios venosos duraís. O quadro clínico é caracterizado por cefaleia, tinnitus, náuseas, vômitos e distúrbios visuais. O tratamento inicial consiste em uma modalidade clínica, e quando esta é ineficaz, há indicação de procedimentos invasivos, dentre os quais estão as...
derivation of visual acuity due to chronication. The diagnosis is made through a multidisciplinary neuro-ophthalmological evaluation, with demonstration of papilledema through fundoscopy and of increased ICP by lumbar puncture with measurement of CSF pressure. Concomitantly, other causes of intracranial hypertension should be ruled out through neuroimaging. Magnetic resonance imaging (MRI) of the brain may demonstrate secondary signs of IIH, such as empty sella, posterior flattening of the globe, and increased subarachnoid space around the optic nerve. Brain imaging can demonstrate possible bilateral transverse sinus stenosis.

The clinical picture is characterized by headache of variable intensity (present in up to 94% of patients); tinnitus, which can be unilateral or bilateral; nausea and vomiting; and, most importantly, visual disturbances. These include diplopia (due to involvement of the abducens nerve), papilledema (reflecting increased ICP), and, in some cases, reduction of visual acuity due to chronication. The diagnosis is made through a multidisciplinary neuro-ophthalmological evaluation, with demonstration of papilledema through fundoscopy and of increased ICP by lumbar puncture with measurement of CSF pressure. Concomitantly, other causes of intracranial hypertension should be ruled out through neuroimaging. Magnetic resonance imaging (MRI) of the brain may demonstrate secondary signs of IIH, such as empty sella, posterior flattening of the globe, and increased subarachnoid space around the optic nerve.

Angioplasty of the venous sinuses, when indicated, is an alternative that provides better outcomes with fewer complications than conventional surgical treatments. We report a case of IIH treated successfully by stent placement for bilateral transverse sinus stenosis, and briefly review the relevant literature.

Case Report
A 27-year-old woman with no past medical history, no comorbidities, and not overweight was referred to the neurosurgery department by her ophthalmologist. She reported a 1-month history of progressively worsening, nonradiating, non-tension-type bifrontal headache without triggering factors. She reported having sought urgent care several times due to recurrent headache. She noticed a gradual deterioration of visual acuity and then saw an ophthalmologist, who detected bilateral papilledema and promptly referred her to our service for evaluation.

A magnetic resonance imaging (MRI) of the brain showed no space-occupying lesions and no signs of hydrocephalus or of demyelination. Magnetic resonance angiography of the cerebral circulation ruled out cerebral venous thrombosis, but demonstrated possible bilateral transverse sinus stenosis.

A diagnosis of IIH was suggested due to the refractory symptoms of the patient, to the neuroimaging findings, to the evidence of increased ICP, and to the persistent visual deficit. To confirm this hypothesis, lumbar puncture was performed, which showed an opening CSF pressure of 37 cmH₂O. Approximately 40 mL of CSF were drained; after the procedure, the patient reported substantial improvement of the headache.

We decided on a trial of clinical treatment and prescribed acetazolamide 250 mg every 6 hours. There was slight improvement of the headache, but no improvement of the visual deficit; in addition, the patient experienced several adverse effects, including abdominal discomfort, nausea, vomiting, and postural hypotension.

After discussing additional therapeutic options with the patient, we decided to perform angiography to determine the trans-stenotic pressure gradient. If there was a change of > 8 mmHg, stent placement would be indicated. The angiogram revealed bilateral transverse sinus stenosis (Fig. 1) with a prestenosis venous pressure of 37 mmHg and a poststenosis pressure of 9 mmHg on the right, and a prestenosis pressure of 35 mmHg and a poststenosis pressure of 8 mmHg on the left (pressure differential, 28 mmHg on the right and 27 mmHg on the left). Intravenous ultrasound confirmed bilateral venous narrowing (Fig. 2). With confirmation of the large bilateral pre- and poststenosis pressure gradient, stents were placed in both transverse sinuses. After the procedure, a new pressure gradient measurement was performed and revealed a significant reduction, with a prestenosis pressure of 11 mmHg and a poststenosis pressure of 9 mmHg in the right transverse sinus. On the left, the prestenosis and poststenosis measurement was 11 mmHg and 10 mmHg, respectively. In the immediate postoperative period, the patient reported slight worsening of her headache, possibly due to the manipulation of the venous system, which improved gradually with corticosteroids. She had an uneventful course and was discharged early free of pain.

At the outpatient follow-up 2 weeks after the procedure, the patient reported no pain. Recovery of visual acuity...
followed at \( \sim 1 \) month. Repeat ophthalmologic evaluation demonstrated complete resolution of the papilledema. At the time of writing, 6 months after the procedure, the patient is symptom-free. Clinical follow-up with the neurosurgery and ophthalmology teams is ongoing; we have not performed control angiogram or lumbar puncture, which would be unjustifiable in an asymptomatic patient.

**Procedure**

The patient began dual antiplatelet therapy (aspirin 100 mg/day and clopidogrel 75 mg/day) 5 days before the procedure. First, conscious sedation was administered for the measurement of pressure gradients. Access was achieved through the right femoral artery with a 5F sheath for angiographic control and road mapping, and through the left femoral vein with a 6F sheath for stent placement. A bolus injection of 5000 IU of unfractionated heparin was administered, and a 6F guide catheter was advanced to the right jugular bulb. A 0.027-inch Rebar microcatheter (Medtronic, Minneapolis, MN, USA) was passed coaxially, over a 0.014-inch Hybrid microguidewire (Balt Extrusion, Montmorency, France), to the sites designated for pre- and poststenosis pressure measurement, with the results described above.

With the confirmation of gradients > 8 mmHg, general anesthesia was induced for stent placement. The 6F venous introducer was replaced with a 60-cm 10F sheath, and a 90-cm 8F guide catheter was passed coaxially over a 0.35-inch hydrophilic guidewire and was advanced to the right jugular bulb. Then, a 0.014-inch BMW Extra Support microguide (Abbott, Chicago, IL, USA) was passed up to the poststenotic segment of the left transverse sinus. A 9 \( \times \) 30 mm Wallstent (Boston Scientific, Marlborough, MA, USA) was navigated and deployed to cover the stenosis on the left side. A 9 \( \times \) 40 mm Wallstent (Boston Scientific, Marlborough, MA, USA) was then navigated through the same system and deployed to cover the contralateral stenosis (Fig. 3). No balloon dilation was performed. Finally, a 0.027-inch Rebar catheter (Medtronic, Minneapolis, MN, USA) was again navigated for repeat measurement of the venous pressures, which showed normalization of the gradients. The patient completed a 30-day course of dual antiplatelet therapy, after which clopidogrel was discontinued. She continues to take aspirin (100 mg/day).

Discussion

The first line of IIH treatment is clinical, and consists of weight reduction, adequate diet, analgesics to relieve headache, and carbonic anhydrase inhibitors such as acetazolamide (1.5 to 3 g/day divided into 3 or 4 doses) or methazolamide (50 to 300 mg/day); furosemide or topiramate may be used as a second option in some cases.\(^8,9\) Obesity plays an important role both in the development of IIH and in its refractoriness to treatment. Excess weight is believed to result in increased intrathoracic pressure, which impairs venous drainage of the head and of the neck, consequently leading to an increase in ICP.\(^10\)

Surgical treatment is reserved for cases with symptoms refractory to conservative management or rapid, significant deterioration of visual acuity. The recommended modalities are optic nerve sheath fenestration (ONSF) or shunting (ventriculoperitoneal, lumboperitoneal).\(^11\) In recent years, venous angioplasty has gained an increasing role in the treatment of this disease, with promising results and low morbidity and mortality,\(^12\) providing a minimally invasive and highly effective alternative to the usual surgical procedures. Whether dural venous stenosis is a cause or a consequence of IIH remains unknown. The most accepted theory is that intracranial hypertension causes extrinsic compression of the dural venous sinuses.\(^13\) Venous stenting both relieves this compression and reduces ICP.\(^14\) Conversely, medical management and CSF drainage have no impact on venous stenosis, even when ICP improves.\(^15\)

In our case, we chose to perform the pressure measurements with conscious sedation because some studies have

shown that general anesthesia causes a substantial decrease in the pressure gradient of the venous system, which may bias the results of the procedure.\(^{16}\) Once the gradient had been confirmed, we switched to general anesthesia for patient comfort, as manipulation of material within the venous system can cause considerable pain.

In most cases, dural venous stenosis occurs in the transverse sinus, and in between 70 and 80% of the cases, it is bilateral. This raises another question: should angioplasty be performed bilaterally or only in the dominant sinus? Koovor et al\(^{17}\) described a series of 16 treated patients, of whom 75% had bilateral transverse sinus stenosis; nevertheless, in all of the cases, only the dominant sinus was treated. Headache improved in 10 patients, and the papilledema improved in all of them. No complications were reported. In our case, although the right transverse sinus was dominant, there was abundant flow to the left, and the pressure gradient on this side was also quite considerable, which is why we chose to place stents bilaterally. From a technical standpoint, it was easy to pass the stent from right to left and to deploy it in the craniocaudal direction, and easier still to then pass the other stent and to treat the stenosis ipsilateral to endovascular access.

Several studies have compared treatment alternatives for dural venous stenosis. A meta-analysis published in 2015\(^{18}\) compared outcomes in 136 patients who were treated with angioplasty, 712 with ONSF, and 435 with CSF shunt placement. In the ONSF group, there was improvement of vision in 59%, of headache in 44%, and of papilledema in 80%. In the CSF shunt group, there was improvement of vision, headache, and papilledema in 54%, 80%, and 70%, respectively, while in the angioplasty group, there was improvement of vision, headache, and papilledema in 78%, 83%, and 97%, respectively. The complication rates were 18% in the ONSF group, 40% in the CSF shunt group, and 7.5% in the angioplasty group. These findings confirm the greater success and lower complication rates of angioplasty.\(^{19}\)

- Table 1 describes major case series of patients treated with dural venous angioplasty, demonstrating low rates of complications and high rates of symptomatic improvement.\(^{21−27}\) Most of the complications reported were related to vascular access, such as local hemorrhage and pseudoaneurysm, rather than to stent implantation. Ducruet et al,\(^{20}\) in their series of 30 cases, reported intrastent stenosis in 4 patients, and proximal stent stenosis in 5. None of these required new stent implantation, and five patients did undergo CSF shunt placement. A recent meta-analysis\(^{28}\) of 473 patients reported restenosis in 14% of the cases, most of them proximal or distal to the stent. The mechanisms judged most likely by the authors were intimal hyperplasia or simply because extrinsic intracranial hypertension continued to compress the sinuses. Thus, it seems plausible that using longer stents could reduce the rate of restenosis.

Over the years, the endovascular approach has emerged as the leading treatment modality for IIH, instead of as an alternative to surgery. Cappuzzo et al. proposed an algorithm whereby, in case of confirmed diagnosis and failure of medical management, or if there is rapid visual deterioration, digital subtraction angiography with pressure gradient measurement should be performed. If a gradient > 8 mmHg is present, stenting is indicated; if symptoms recur or if there is no improvement, only then is surgical shunting to be considered. Most of the current literature suggests that failure post stenting should be treated exactly thus.

However, if many patients have bilateral transverse sinus stenosis and the standard treatment is to perform angioplasty only on the dominant side, should this subgroup of patients not benefit from stenting of the other sinus before thinking of surgical shunting? There have been reports of patients requiring retreatment because of restenosis of the previously treated side, but stenting of the contralateral transverse sinus was not attempted. We believe there is a subgroup of patients that might benefit from bilateral sinus stenting, but comparative studies are needed to support this theory.

Conclusion

Transverse sinus angioplasty seems to be a safe and relatively simple procedure for the treatment of IIH, with very good short-term outcomes and low complication rates. Additional research is needed to confirm these findings.
