Bilateral basal ganglia bleed, though common in hypertensive, is unusual in posttraumatic patients. Bilateral basal ganglia hematoma following trauma is extremely rare and is limited to few case reports. The authors report three cases of bilateral basal ganglia hematomas in traumatic patients. All the cases were managed conservatively.

Introduction

Traumatic basal ganglia hematoma is defined as hemorrhage in the basal ganglia or its neighboring structures such as the internal capsule or thalamus. Incidence of 3 to 10% of head injuries are reported. Bilateral basal ganglia hematoma is extremely rare and is limited to few case reports. Mechanism of basal ganglia bleed is unclear but is hypothesized to arise from sheer strain on the lenticulostriate arteries or anterior choroid vessels, caused by acceleration and deceleration forces at the time of injury. Its importance arises in the medical legal cases in which it may be taken as a nontraumatic bleed.

Case Report

Case 1

A 34-year-old man alleged to have sustained injuries in a road traffic accident (RTA) due to a fall from a two-wheeler while driving in a drunken state, was hospitalized in an unconscious state. There was history of loss of consciousness since the time of fall. There was no history of vomiting, seizures, ear/nose bleed, and cerebrospinal fluid leak following the accident. No history of a significant medical/surgical illness was reported.

On examination, the patient's Glasgow coma scale (GCS) score was E1V1M3. There was left hemiplegia. Blood pressure and pulse rate were within normal limits. The patient was intubated and put on mechanical ventilator. A computed tomography (CT) scan of the brain revealed bilateral hyperdense hemorrhagic lesions in the basal ganglia regions (Fig. 1). Blood parameters were within normal limits.

After stabilizing, the patient was shifted to neurosurgery intensive care unit (ICU) and put on antiepileptics, decongestants such as furosemide and mannitol 20%, and antibiotics. He was continued on mechanical ventilator, and tracheostomy was done later. He deteriorated neurologically in the

It has also been postulated that if trauma occurs it can be classified as large if it is greater than 2 cm in diameter and small if lesser than 2 cm in diameter. Coup and countercoup can cause this, and this may cause bilateral lesions. It is defined as hemorrhage in the basal ganglia and its neighboring structures such as the internal capsule and thalamus. Bilateral basal ganglia bleed is extremely rare and is restricted to few case reports. It is defined as hemorrhage in the basal ganglia and its neighboring structures such as the internal capsule and thalamus. It can be classified as large if it is greater than 2 cm in diameter and small if lesser than 2 cm in diameter.

The mechanism of traumatic basal ganglia bleed is unclear. It is most likely to be caused by shearing injury to the anterior choroidal artery and lenticulostriate artery as a result of acceleration and deceleration forces brought about by high-velocity injuries resulting in hemorrhages in basal ganglia. It has also been postulated that if trauma occurs when head is in motion, and if the impact is adequate to deform the skull is applied to the vertex, forehead, or the occipital region and directed to the tentorium, it shifts the brain through the tentorial notch producing shearing forces leading to tearing of the lenticulostriate arteries. Coup and countercoup can cause this, and this may cause bilateral lesions.

Here in this series, all the three cases sustained head injuries following fall from a two-wheeler, which establishes the nature of the basal ganglia bleeds. All the patients were non-hypertensive, and their blood pressures were within normal range during the length of stay, which reinstates the nature of bleeds in these cases.

Treatment options for basal ganglia hematoma include conservative, open surgery, and stereotactic guided/ultrasound-guided aspiration. Boto et al recommended surgical evacuation for all the lesions with a volume greater than 25 mL. Surgical evacuation was not required in any of cases in this study as intracranial pressure could be controlled under safe limit by pharmacologic means and ventilator support.

The outcomes of traumatic basal ganglia bleed have been found to be variable. The prognosis is variable and dependent on many factors such as size, associated coagulation disorders, diffuse axonal injury, age more than 60 years, and associated bleeds such as intraventricular bleeds.

Jain and colleagues reported a 38-year-old conscious man, who presented with bilateral basal ganglia hematoma and extradural hematoma. The patient underwent craniotomy and hematoma evacuation. Another recent report by Kaushal et al included a 42-year-old male patient who suffered RTA and was hospitalized with a GCS score of 5. An isolated bilateral (mirror-image) traumatic basal ganglia bleed was revealed on CT scan of the brain.

**Case 2**

A 40-year-old man alleged to have sustained injuries in a RTA due to a fall from a two-wheeler under influence of alcohol presented to emergency department with complaints of loss of consciousness, vomiting, and ear bleed. The patient was nonhypertensive and nondiabetic. On examination, he was unconscious with a GCS score of E1V1M5 without any motor deficits. Pupils were mid-dilated and symmetrically reacting to light. CT scan of the brain revealed bilateral basal ganglia hematoma associated with right frontal contusion (Fig. 2). He was intubated and put on mechanical ventilator and under the coverage of decongestants and antiepileptics. He was tracheostomized on day 4 and then weaned of the ventilator on day 7. The patient gradually regained conscious and his GCS score improved to E4V4M6. He was discharged under the coverage of antiepileptics.

**Case 3**

A 40-year-old woman, farmer by occupation, was brought to the emergency department by relatives with complaints of loss of conscious and vomiting following a fall from a two-wheeler as a pillion rider. On examination, the patient was drowsy with a GCS score of E3V2M5 without any motor deficits. Pupils were mid-dilated and symmetrically reacting bilaterally. She was non-hypertensive and non-diabetic. CT of the brain revealed hyperdensities in the basal ganglia region bilaterally (Fig. 3). She was shifted to neurointensive care and was put on decongestants (mannitol) and antiepileptics (phenytoin). She gradually improved to a GCS score of E4V5M6 and was discharged after 20 days under coverage of antiepileptics.

**Discussion**

Hypertensive hemorrhage is common in the basal ganglia, most often restricted to one side. Traumatic basal ganglia bleed is uncommon, and its incidence among closed head injuries is reported as 3% in few case series. Bilateral basal ganglia bleed is extremely rare and is restricted to few case reports. It is defined as hemorrhage in the basal ganglia and its neighboring structures such as the internal capsule and thalamus. It can be classified as large if it is greater than 2 cm in diameter and small if lesser than 2 cm in diameter.

The mechanism of traumatic basal ganglia bleed is unclear. It is most likely to be caused by shearing injury to the anterior choroidal artery and lenticulostriate artery as a result of acceleration and deceleration forces brought about by high-velocity injuries resulting in hemorrhages in basal ganglia.

**Fig. 3** Computed tomography showing two hyperdense lesions on the right and one hyperdense lesion on the left side in the basal ganglia regions.
The patient was discharged on the 14th day. Bhargava et al reported two cases of bilateral basal ganglia bleed in 25- and 50-year-old men who suffered RTA and were admitted with GCS scores of 4 each. Both were managed conservatively and discharged.

Outcome of traumatic basal ganglia hematomas has been found to be variable. Among 37 patients studied by Boto et al, 59% died, 5% were vegetative, 19% experienced severe disabilities, and 16% made a favorable recovery. Katz et al, Jang et al, Kimura et al, and Lee and Wang have also reported good prognosis for traumatic basal ganglia hematomas. Prognosis of traumatic basal ganglia bleeds is good on comparison with other hematomas, which has been supported by all the studies.

**Conclusion**

Traumatic basal ganglia bleeds are rarely reported, and bilateral basal ganglia bleeds are extremely rare. It can be managed conservatively more often, and the prognosis is also variable.
