Abstract

Pemphigus vulgaris is an autoimmune disease characterized by fluid-filled blisters over body and mucosal surfaces. Localized pemphigus is a rare presentation of the disease. There are few reports of localized pemphigus in literature presenting as esophageal involvement, recurrent paronychia, conjunctival mass, foot ulcers, discoloration of toes with hyperkeratotic skin lesions, verrucous lesions, and dyshidrosiform pemphigus vulgaris. We present a case of dyshidrosiform pemphigus involving a foot following trauma. Histopathology and direct immunofluorescence confirmed our diagnosis. In our patient, the disease started as localized dyshidrosiform pemphigus and later became generalized. This unusual presentation led to a delay in diagnosis and proper treatment in this patient. Physicians should be aware of such rare presentations to aid in the timely diagnosis and management of such patients.

Pemphigus vulgaris is an autoimmune bullous disease clinically characterized by flaccid cutaneous blisters and erosions with mucosal involvement. Unilateral or localized forms of pemphigus have been reported in literature. Some rare presentations of pemphigus vulgaris include isolated esophageal involvement, recurrent paronychia, conjunctival mass, foot ulcers, discoloration of toes with hyperkeratotic skin lesions, verrucous lesions, and dyshidrosiform pemphigus vulgaris. We present a case of unilateral dyshidrosiform pemphigus vulgaris following limb trauma.

A 35-year-old man presented with tense as well as flaccid vesicular lesions and crusting on right foot. A known case of pemphigus vulgaris for past 10 years, he had been treated with dexamethasone pulse therapy and azathioprine, followed by rituximab. He was in remission for past 3 years before this episode. Four months back he had fracture right femur for which he was operated and internal fixation of fracture was done. Four weeks following the surgery, he developed vesicular lesions on his right sole followed by crusting. He was being treated as infected eczema from another facility with oral antibiotics and prednisolone with minimal relief. Subsequently, he developed flaccid vesicles on the scar of surgery for fracture. There was no lesion elsewhere in the body. Two months later, he developed oral erosions and few similar lesions on upper trunk and upper limbs. On examination, there were tense vesicles and yellowish brownish crust on the right sole and its lateral margin (Fig. 1). Flaccid fluid-filled vesicles and erosions were present at the scar site (Fig. 2). Few scattered lesions were seen on the chest, abdomen, upper back, and upper limbs. Differential diagnoses at the time of presentation included localized dyshidrosiform pemphigus vulgaris, vesicular eczema, bullous tinea pedis, and bullous erythema multiforme.

Tzanck smear from lesions on sole, scar area, and oral mucosa showed acantholytic cells. Histopathology (Fig. 3A) and direct immunofluorescence (Fig. 3B) were suggestive of pemphigus vulgaris. With a diagnosis of dyshidrosiform pemphigus vulgaris followed by generalization, he was treated with prednisolone 40 mg/day and subsequently with rituximab 1 g two doses 2 weeks apart and had improvement.

Dyshidrosiform pemphigoid is a well-known variant of localized pemphigoid presenting as vesiculobullous lesions on palms and soles.1 Dyshidrosiform pemphigus, however, is rarely seen (Table 1). Palmoplantar involvement in pemphigus vulgaris is a poor prognostic indicator.3 The presentation
Unilateral Dyshidrosiform Pemphigus Vulgaris

Fig. 1 Tense blisters and crusting on sole of right foot and lateral margin.

Fig. 2 Flaccid clear fluid filled blister on scar area on right thigh.

Fig. 3 (A) Histopathology (hematoxylin and eosin stain, 20X magnification) shows suprabasal cleft with row of tombstones and mild perivascular inflammatory infiltrate in dermis. (B) Direct immunofluorescence study highlights intraepidermal deposition of immune-reactant in fishnet like pattern.
in our patient was unusual as the disease relapsed as pompholyx like lesions, initially confined to the limb that had sustained trauma. Exact pathogenesis of dyshidrosiform pemphigus is unknown. This presentation can be explained by the hypothesis proposed in dyshidrosiform pemphigoid. Local inflammatory process can uncover the masked antigen and trigger the disease at local site. Our patient had trauma in his right limb followed by internal fixation of fracture. This may have led to inflammation and local edema that might have triggered an inflammatory response unmasking or modulating pemphigus antigen similar to Koebner’s phenomenon. In a report of dyshidrosiform pemphigoid secondary to venous stasis, the pathogenesis was attributed to local inflammation analogous to koebnerisation. Dyshidrosiform pemphigoid can precede or occur concurrently with generalized form.

In our patient, the disease started as localized dyshidrosiform pemphigus and later became generalized. Other possibilities considered in our patient were infected dyshidrosiform eczema, bullous tinea pedis, and bullous erythema multiforme. Dyshidrosiform eczema and bullous erythema multiforme is usually bilateral and was excluded based on Tzanck smear positivity and histopathology/direct immunofluorescence characteristic of pemphigus. Tinea pedis was ruled out with the help of potassium hydroxide mount examination of blister fluid that was negative.

This unusual presentation led to a delay in diagnosis and proper treatment in this patient. This case is being presented to highlight a rare morphologic variant of pemphigus.
