Practical Recommendations for the Management of Benign Adnexal Masses

Recomendações práticas para o tratamento de massas anexiais benignas

Abstract

Objective To perform a comprehensive review to provide practical recommendations regarding the diagnosis and treatment of benign adnexal masses, as well as information for appropriate consent, regarding possible loss of the ovarian reserve.

Methods A comprehensive review of the literature was performed to identify the most relevant data about this subject.

Results In total, 48 studies addressed the necessary aspects of the review, and we described their epidemiology, diagnoses, treatment options with detailed techniques, and perspectives regarding future fertility.

Conclusions Adnexal masses are extremely common. The application of diagnosis algorithms is mandatory to exclude malignancy. A great number of cases can be managed with surveillance. Surgery, when necessary, should be performed with adequate techniques. However, even in the hands of experienced surgeons, there is a significant decrease in ovarian reserves, especially in cases of endometriomas. There is an evident necessity of studies that focus on the long-term impact on fertility.

Keywords ► adnexal masses ► ovarian cysts ► ovarian surgery ► ovarian reserve ► infertility ► fertility preservation

Resumo

Objetivo Realizar uma revisão abrangente para fornecer recomendações práticas sobre o diagnóstico e tratamento de massas anexiais benignas, bem como informações para um consentimento adequado com relação à possível perda da reserva ovariana.

Métodos Uma revisão abrangente da literatura foi realizada para identificar os dados mais relevantes sobre o assunto.

Resultados No total, 48 estudos abordaram os aspectos necessários da revisão, e descrevemos sua epidemiologia, diagnósticos, opções de tratamento com técnicas detalhadas, e perspectivas sobre fertilidade futura.

Conclusões As massas anexiais são extremamente comuns. A aplicação de algoritmos de diagnóstico é obrigatória para excluir a malignidade. A maioria dos casos pode ser manejada conservadoramente. A cirurgia, quando necessária, deve ser realizada com técnicas adequadas. No entanto, mesmo nas mãos de cirurgiões experientes, há diminuição significativa da reserva ovariana, principalmente nos casos de endometriomas. Há uma evidente necessidade de estudos que enfocem o impacto das massas anexiais benignas na fertilidade em longo prazo.

Introduction

Benign adnexal masses are extremely common during a woman’s life. Up to 10% of them will undergo surgery due to some adnexal mass throughout their lifetime. Because it is a benign disease, the surgical treatment may seem deceptively simple. How can we properly inform patients who are concerned about fertility?

Despite the high prevalence of this condition and the number of surgical procedures, a significant part of the patients does not seem to receive enough information for appropriate consent regarding possible loss of the ovarian reserve. There is evidence of negative impact on ovarian reserve due exclusively to the presence of cysts and perhaps more markedly in endometriotic cysts. In addition, a considerable proportion of these patients will undergo surgery that could potentially compromise even more the ovarian function.

It is extremely important that the attending physician has a critical view of the difficulties in assessing adnexal masses, the consequences of the clinical and surgical treatments, and the current possibilities of gauging the ovarian reserve, since the treatments and the different techniques may interfere on fertility in the long term.

The objective of the present review is to provide the gynecological surgeon with fundamental elements for a better understanding of the decision-making process in the treatment of adnexal pathologies and the best possible counseling for women about the risks and benefits of these treatments in their reproductive future. The establishment of appropriate surgical routines that consider the preservation of fertility is of major importance.

Methods

The data were obtained through a bibliographic research in the Medline, LILACS and Scielo databases. We performed the search using the terms “ovarian cyst,” “adnexal mass,” “ovarian reserve,” “ovarian surgery,” “infertility” and “fertility preservation.” All identified articles were published in English in the past 15 years (between January 2004 and April 2019). The articles that had as their central topic benign ovarian pathologies and their relationship with alterations in the ovarian reserve and preservation of fertility were included.

Results

A total of 48 articles published between 2004 and 2019 fulfilled the inclusion criteria. The information was analyzed for the consistency of the data, the year of publication, and the quality of the study. Articles that did not address directly the review objectives were excluded.

Discussion

Epidemiology

The ovarian cyst is defined as a structure that contains fluid and has more than 30 mm in diameter. A significant part of the ovarian cysts is asymptomatic, which can lead one to underestimate the real incidence. It is estimated that, in the United States, 250 thousand women per year are hospitalized due to adnexal masses.

According to a population-based cohort with 11,595 patients from 1991 to 2014, the incidence of ovarian cysts increases exponentially with age. There is an incidence plateau around the age of 26, reaching 152 cases per 100 thousand women per year at 35 years old, which is maintained throughout the menopause.

Just over a third of the benign masses were epithelial lesions (35.1%). Almost a third were tumor like lesions (32.8%), being functional cysts and endometriotic cysts. 29.8% were germ-cell tumors (almost entirely mature teratomas), and a small fraction of 2.3% were stromal tumors (mostly fibromas/tecomas). The exact proportions are shown in Fig. 1.

At menopause, most of the masses are benign, and the chance of developing malignancy of the symptomatic cysts is around 1: 1 thousand. The incidence of borderline malignancies and tumors follows the same behavior with regard to the incidence plateau; however, it is of around 8 cases per 100 thousand women per year. Therefore, the proportion of malignancies among all ovarian neoplasms is of ~3%. In the pediatric range, the common symptoms are acute and chronic abdominal pain, presence of abdominal mass, and abdominal distension. Germ-cell tumors are more common, with teratomas being the main representatives. Physiological cysts in premenarchal girls are rare, and it is estimated that the prevalence of malignancy does not exceed 15%.

Diagnostics

We can conclude from the previous section that, in fact, the chance of facing malignant adnexal pathologies is relatively low. Despite this, the identification of malignant neoplasms is mandatory. The difficulty in establishing a reasonable means of screening for ovarian malignancies is widely known. Most ovarian cancers are not diagnosed in the early stages (15% in stage I), even in the menopausal period, when the incidence of this type of malignancy increases.

Many models have been proposed to screen patients for appropriate treatment, but none of them was able to be unanimously accepted. The details of the various models are beyond the scope of the present review, but they may include: the Risk of Malignancy Index (RMI); the National Institute for Health and Care Excellence (NICE) Guidelines; the Risk of Ovarian Malignancy Algorithm; Logistic Regression (LR); and methods based on ultrasound criteria proposed by the International Ovarian Tumor Analysis (IOTA); Simple Rules (SRs); Simple Rules Risk (SRR); and Assessment of Different Neoplasms in the Adnexa (ADNEX).

Despite some modifications over the years after the creation of the RMI, it remains as the alternative with the best validation. It consists of the product between the level of carcinoembryonic antigen 125 (CA-125), hormonal status (M) and ultrasound scoring (U): RMI = CA-125 x M x U (Table 1).

In order to create an adequate screening workup, the use of a specific set of ultrasound characteristics to predict malignancy of the adnexal masses named the “Simple Rules"
SRs) was recently proposed. The concept is based on the identification of basic benign and malignant echography features (Box 1).

Eight years later, in 2016, a large multicenter cross-sectional study involving 22 research centers with 4,848 patients aimed to evaluate the efficacy of the SRs in the prediction of malignancy of adnexal masses. For the 1% risk cutoff, the sensitivity was of 99.7%, the specificity was of 33.7%, the LR was of 1.5 and -0.010, the PPV was of 44.8%, and the NPV was of 98.9%. For the 30% risk cutoff, the sensitivity was of 89.0%, the specificity was of 84.7%, the LR was of 5.8 and -0.13, the PPV was of 75.4%, and the NPV was of 93.9%.

The use of SRs was subsequently validated considering their performance in the diagnosis of early ovarian malignancies, even when compared with the other models proposed by the IOTA. At this point, we highlight the high NPV (98.9%) of the SRs in scenarios of low risk of malignancy.

After the application of the screening methods, the patients whose initial evaluation reveals high risk for malignancy should ideally be treated in specialized centers with a multidisciplinary team, maximizing the oncological results and making it possible to discuss options to preserve fertility.

**Ovarian Reserve**

There is currently no ideal method to predict the ovarian reserve, and some important aspects should be considered. Estimates of the ovarian reserve are performed mainly by the measurement of the antimullerian hormone (AMH) and the antral follicle count (AFC). The AMH is produced by granulosa cells from active follicles, and can be dosed in the peripheral blood. The production of AMH is stable throughout the menstrual cycle, and is the first to change with advancing

Treatment

Surveillance

A significant proportion of the benign ovarian masses will present spontaneous resolution. Therefore, the expelling conduct may be of extreme validity, avoiding unnecessary surgeries, and, consequently, additional damage to healthy ovarian tissue. Functional cysts or simple ovarian cysts (anechogenic, thin-walled and smaller than 50 mm) usually resolve after 3 menstrual cycles without the need for any intervention.

Management of the Risk of Adnexal Torsion

After the decision regarding surveillance, the risk of adnexal torsion remains a concern. In an international prospective cohort, among the patients selected for conservative management and surveillance, the overall risk for torsion was of around 4%.

A case series with 360 patients showed that the main pathologies associated were dermoid cysts (36%), follicular cysts (16.1%), corpus luteum cysts (9.9%), and serous cystadenoma (9.9%), with an overall mass size ranging from 8 cm to 15 cm. Functional cysts or simple ovarian cysts (anechogenic, thin-walled and smaller than 50 mm) usually resolve after 3 menstrual cycles without the need for any intervention.

An interesting proposal in the symptomatic pediatric/adolescent range is a composite score of risk. It consists of identifying and scoring the presence of independent risk factors: absence of vomiting (zero points) or presence of vomiting (2 points); ovarian volume higher than 17 mL (premenarchal: 2 points) or 105 mL (menarchal: 2 points); adnexal ratio (volume of the affected ovary divided by the contralateral ovary) higher than 21 (2 points). For scores ≥ 4, surgical treatment is recommended. Even with scores between 2 and 3, until 10% of the patients presented with torsion.

Regarding Endometriomas

A study monitored 1,199 cycles of 244 patients with unilateral endometriomas, comparing ovulation between the healthy and the affected ovaries. Documented ovulation did not differ (49.7% versus 50.3% respectively), even with cysts with more than 6 cm in diameter. In total, 43% of the patients conceived spontaneously during the study period of 4 years. There is no relevant data on the literature that supports that systematic surgical removal of cysts smaller than 4 cm prior to assisted reproduction procedures. Expectant behavior is also justified in this scenario. Other aspects regarding the management of endometriomas will be further discussed, but surveillance seems to be the main approach.

Oral Contraceptives

A systematic review that analyzed eight randomized trials concluded that, although widely used in the clinical practice, the prescription of oral contraceptives does not influence the resolution of functional cysts. The outcomes are the same for both spontaneous cysts and those caused by ovulation-induction processes. Persistent cysts tend to be pathological rather than physiological.

Surgical Approach - Technical Considerations

The indication of surgery occurs when: there is uncertainty regarding the suspicion of malignancy; the size of the adnexal mass increases the risk of pain and torsion episodes; the augmentation of the mass might compromise the ovarian follicles; and, in cases of endometriotic cysts, when there is a progressive increase in volume and pelvic pain due to endometriosis. Once the need for intervention is defined, one should consider several technical details that can minimize the impact on the ovarian reserve and improve the overall outcome of the surgery.

Laparoscopy

The body of evidence in favor of the laparoscopic approach is significant when there is a need for surgery. Laparoscopic cystectomy is often the rule, to minimize potential complications such as ruptures in malignant situations, and to optimize fertility preservation. This technique is well established as the gold standard in this set of pathologies.

Comparison of Etiologies

Despite the fact that the multitude of etiologies of the ovarian masses and the surgical practice demonstrate evident technical differences among the different types of cysts, the damage to the ovary is evident and unavoidable in every situation.

The comparison of the levels of AMH, FSH, AFC, ovarian volume and vascularization did not show significant differences when comparing the group with bilateral endometriomas (∅ = 21), unilateral endometriomas (∅ = 29), other benign cysts (∅ = 20), and the control group without cysts (∅ = 20), when the laparoscopic surgery was performed with hemostatic sutures. The small difference observed was in the first postoperative month, but did not remain after 12 months.

Comparing the levels of AMH and the amount of remaining follicles in the surgical specimen, no differences were
found between patients with endometriomas (n = 68) and other benign cysts (n = 32). Bilaterality was the only risk factor associated with greater loss of ovarian reserve.28

In a study29 with 71 patients, the final volume was lower (2.41 mL versus 2.23 mL, p = 0.49), as compared with the non-operated ovary, as well as the AFC (3.45 versus 2.43, p = 0.11), regardless of the fact that there were endometriotic cysts or not. Ovarian volume and CFA differences were not dependent on the size of the cysts.29

Contrasting this scenario, in a study30 comparing the AMH levels of patients with endometriomas, other benign cysts and patients with infertility of tubal cause, endometriomas show a different behavior from the other benign cysts, since AMH levels may be lower than in the other conditions (1.53 ng/mL, 2.20 ng/mL, and 2.82 ng/mL respectively). Surgery significantly decreases the levels of AMH in the case of endometriomas (worse if bilateral) compared with other pathologies.30

In a study4 with 75 patients (33 teratomas, 25 endometriomas, 9 functional cysts, and 8 cystadenomas) the reduction in the levels of AMH was different, depending on the histological diagnosis of the mass. Patients with endometriomas had a faster and longer lasting reduction in AMH levels: a 51-% mean reduction 6 months after surgery (p = 0.007). Patients with teratomas presented a 25-% reduction (p = 0.009). In the other patients, the reduction was of 34% (p = 0.059).4

In a study31 with 22 patients, 12 with endometriomas and 10 with non-endometriotic cysts, there was a reduction in the levels of AMH postsurgery (5.48 ng/mL before and 2.56 ng/mL after; p < 0.05), but without changes in the AFC, estradiol and ovarian volume. This decrease occurred at the expense of the group of patients with endometriomas. A technique of bipolar hemostasis associated with hemostatic suture was used.31

A retrospective study3 of 97 patients aged between 20 and 39 years showed that AMH levels are lower in patients with endometriomas compared with other benign cysts (4.12 ng/mL versus 6.02 ng/mL; p < 0.001). The mean level of AMH was also lower the diameter of the non-endometriotic mass.3

In a case-control study32 with 56 patients with endometriomas and 16 patients with other benign cysts, there was a significant decrease in AMH levels after surgery (stripping cystectomy with bipolar hemostasis) in the group with endometriosis (4.3 ng/mL versus 2.8 ng/mL; p < 0.001), but the same did not occur in the group of other benign cysts (5.6 ng/mL versus 4.9 ng/mL; p = 0.251). This drop was also more significant in the group with endometriosis of stages III to IV (4.26 ng/mL versus 2.62 ng/mL; p < 0.001) when compared with the group with endometriosis of stages I to II (4.38 ng/mL versus 3.34 ng/mL; p = 0.66).32

Another retrospective study33 with 138 women submitted to salpingectomy, 36 submitted to unilateral salpingo-oophorectomy, 40 who underwent excision of an endometrioma, and 41 who underwent cystectomy due to other causes showed no difference in the levels of AMH (p = 0.33), AFC (p = 0.59) and FSH (p = 0.21) between the salpingectomy group and the group who did not undergo surgery. The group submitted to unilateral salpingo-oophorectomy had lower levels of AMH (-54%; p = 0.001). Women with endometrioma also had lower levels of AMH (-66%; p = 0.002), but this did not affect the AFC (p = 0.22) and FSH (p = 0.28).34

Recently, a study performed in patients34 with endometriomas (n = 34) and other benign masses (n = 18) showed that, 6 months after surgery, the levels of AMH were reduced by 59.3% (p < 0.12) when compared with baseline values in the group with endometriomas, and it was reduced by 29.5% (p < 0.2) in the group with other benign masses. This reduction was not related to the number of follicles inadvertently removed during the procedure (p < 0.669). It is very important to note that, in this study, all procedures were performed by a single specialist surgeon, which indicates that postoperative damage to the levels of AMH is evident, even for surgeons with extensive experience.34

In addition, a retrospective study35 revealed that there are no differences in ovarian stimulation response (measured through retrieved oocytes) in in vitro fertilization (IVF) cycles when there is an evident ultrasound diagnosis of dermoid cyst.35

**Endometriomas - Options of Surgical Techniques and Hemostasis**

Several years ago, some advantages were associated with the excision of an endometriotic cyst when compared with several types of ablative processes. There was an assumption that the excision of the cyst capsule was associated with a lower recurrence of pain symptoms (dysmenorrhea, dyspareunia and acyclic pelvic pain) and less need for further surgeries. In addition, it was associated with a higher rate of spontaneous gestation after the procedure. It was still unclear whether excision was superior to ablative procedures for ART outcomes.36

In 2011, a randomized study36 performed with 48 patients with bilateral endometriomas compared cystectomy and coagulation and found, after cystectomy, a lower antral follicle count (3.67 versus 4.75; p = 0.001), lower ovarian volume (6.27 mL versus 9.87 mL; p = 0.005) and fewer oocytes collected after ovarian hyperstimulation (3.08 versus 3.86; p = 0.01) compared with coagulation alone.36

In a study37 with 25 patients with endometriomas, using only stripping, without coagulation, there was no difference in presurgical AMH levels and 3 cycles after surgery (3.61 ng/mL versus 3.00 ng/mL respectively; p = 0.62).37

In another study38 with 99 patients who underwent surgery for endometriomas, the comparison between cystectomy and bipolar vaporization showed a decrease of more than 50% in AMH levels after surgery. There was no difference between the techniques.38 It is imperative, however, to highlight some limitations of the mentioned study. It was not randomized, did not make a clear separation of the groups, and did not present any follow-up data.

In yet another study,39 45 patients with unilateral endometriomas were treated with laparoscopy and cystectomy with stripping and hemostasis with a dual-wavelength laser (Biolitec Ceralas HPD, wavelength of 980 nm and 1470 nm, model 120 W). The mean level of AMH before surgery was of 3.01 ng/mL; 4 to 6 weeks after surgery, it was of 2.41 ng/mL;
and 6 to 9 months after, it was of 2.7 ng/mL. The decrease was statistically significant (p < 0.05). However, the technique was not compared with stripping alone or with other techniques.

The use of hemostatic sealants was compared with bipolar coagulation in a non-randomized study. The rate of decline in AMH levels was lower using the sealants (15.4%) compared with bipolar coagulation (41.2%; p = 0.003). The levels were measured in 129 patients, without randomization, a follow-up of only 3 months, and other ovarian reserve parameters were not measured.

In a more recent study, 207 patients who underwent excision of endometriomas were followed up for 12 months. The levels of FSH, AMH, the AFC and the PSV were compared regarding 3 different hemostasis techniques: bipolar cauterization (n = 69), ultrasonic scalpel (n = 69) and suture (n = 69). Throughout the period up to the 12th month, the levels of FSH were higher, and the levels of AMH were lower, in the first 2 groups (p < 0.05). At the 12th month, the AFC and PSV were also lower in the first 2 groups (p < 0.05). The authors concluded that bipolar cauterization and the use of ultrasonic scalpel cause more damages to the ovaries when compared with hemostatic suture.

Recently, the laparoscopic stripping of endometriotic cysts became the standard procedure, since it favors a lower recurrence of symptoms and increases pregnancy rates.

Despite this, one cannot deny that surgical damage to ovarian tissue is evident. The histological analysis of the endometrioma capsules revealed the presence of normal ovarian follicles, in a larger quantity the younger the patient and the smaller the cyst diameter.

Those analyses suggest that the intervention leads to the decrease in the ovarian reserve, although the literature is controversial and heterogeneous, especially considering the different methods of hemostasis. The evidence points to a tendency to believe that suture is less harmful to the ovarian reserve.

**Additional Relevant Technical Details**

Following cystectomy, removal of ovarian tissues from the abdomen should preferably be performed through the umbilical portal and wrapped in a protective pouch. This decreases the chance of eventual contamination of the abdominal cavity with the contents of the cyst, and causes less postoperative pain and a shorter recovery time. Transverse minilaparotomy should be considered for the cases of masses with a larger volume (higher than 7 cm in diameter).

The phase of the menstrual cycle for the surgery does not seem to influence the results regarding blood loss and variations in AMH levels. In yet another study, 84 patients in the follicular phase and 71 in the luteal phase were compared after cystectomy for surgical blood loss (p = 0.984) and AMH levels before and 3 months after surgery (p = 0.945); no differences were found by the authors.

During the surgical approach, one should take into consideration the anatomical position of the vascularization of the ovary, aiming at the protection of the pelvic infundibulum from surgical trauma. Interestingly, in a study, the comparison between the excision of dermoid cysts with a mesial approach (33 patients) and an anti-mesial approach (34 patients) showed a higher maintenance of the mean number of antral follicles, a larger mean ovarian diameter, and a higher mean PSV in the ovaries of patients treated with the mesial approach.

**Fertility as the Endpoint**

Interestingly, only one article addressed the main objective of fertility, translated as the birth rates after ovarian surgery. The follow-up of 60 women for 24 months after ovarian surgery demonstrated a significant decrease in AMH levels (2.7 mg/l to 1.1 mg/l; p = 0.001). In total, 36 women tried to conceive, 18 became pregnant, and there were 12 live births. It was possible to determine the behavior of the AMH levels in 34 women who attempted to conceive, and it decreased in both groups (pregnant: 3.3 mg/l to 1.0 mg/l; p = 0.057; not pregnant: 3.2 mg/l to 2.0 mg/l, p = 0.003), but this decrease was not different between the 2 groups (p = 0.112).

**Conclusion**

We conducted a comprehensive review of the literature for the identification of relevant factors regarding the practical recommendations for the treatment of benign adnexal masses and the insights for fertility preservation. The discussion of the subject is extensive, somewhat controversial, but with some points of convergence. In the menopause, after the diagnosis of an adnexal mass, the incidence of cancer is not high, and the use of magnetic resonance imaging (MRI) and 5Rs is satisfactory to predict the risk of developing malignancy. Expectant management can be a valid alternative, avoiding unnecessary procedures, surgical complications, and ovarian changes caused by traumatic injuries. The use of anovulatory medications is, in most cases, unnecessary. Dermoid cysts are more associated with torsion, and masses ranging from 8 cm to 15 cm are more common in this kind of complication. Detorsion is a valid option in cases of functional cysts. The use of composite scores of risk factors in the pediatric/adolescent scenario can aid in the decision for surveillance or surgical treatment. When surgery is necessary, some technical aspects are somehow clearer. The use of videolaparoscopy is well established, in which stripping cystectomy shows better results if we consider all types of masses together. Surgery can be performed at any stage of the cycle. Materials should be removed from the abdomen in protective pouches and, preferably, through the umbilical scar incision. Minilaparotomy is acceptable for masses larger than 7 cm. The mesial approach should be considered in cases of teratomas. The use of bipolar electrocautery appears to have an even more negative impact on AMH levels and the AFC after cystectomies, which may persist for 12 months after the surgical procedure, and should be avoided. Suture is preferable. However, caution should be exercised with such an assertion, given the heterogeneity of the available studies. We emphasize the need for a precise standardization of future studies that involve comparing new hemostasis techniques (when to apply them and if they are necessary at all).
Specifically in the case of endometriomas, the evidence is unclear, but, apparently, there are no changes in the primary ovulatory function of the affected ovaries, but they may be associated with decreased ovarian reserve caused by the disease itself. In addition, the evidence regarding decreased ovarian reserve after the surgical treatment is very strong. Moreover, in view of the recurrence of endometriomas, the second surgery is even more harmful to the AFC. The precise indication and technical quality of the first surgery is fundamental, and successive surgeries should be considered with great caution. Now, there are no standardized protocols to address endometriomas, especially considering the size as the mark of the decision. In regards to fertility, surveillance seems to be the best alternative. Despite some proposals on this subject, the need for future research is evident. Regarding the ovarian reserve, the current difficulties of using markers that are more reliable are clear. Apparently, estimates may be more accurate when counting the antral follicles (which show the direct impact of the affected ovary) in relation to AMH levels (which reflect the pattern of the two ovaries simultaneously). There is a lack of long-term follow-up studies that can elucidate these differences more clearly. Nevertheless, despite the evidence of the decrease in the parameters of evaluation of the ovarian reserve, the question remains: what is the impact of the adnexal masses and their treatments on the real chances of gestation? The data suggest that ovarian reserve evaluations purely based on AMH levels or the AFC may not satisfactorily reflect the actual risks of infertility. It has been suggested that, although objective assessments of the ovarian reserve are of extreme value, it is necessary to prioritize the focus on long-term studies that present the rate of live births as their endpoint. Therefore, we suggest great caution and care when clarifying the best possible evidence for patients with adnexal masses, revealing our limitations. In this way, we will be able to offer the necessary data about the reproductive future and the adequate information for the correct decision making regarding the patients who need treatment for adnexal pathologies.

Conflicts of Interest
The authors have none conflict to interests to declare.
