Abstract

Chronic subdural hematoma (CSDH) is one of the most frequent benign neurosurgical pathologies. Burr hole drainage is known to be safe, with low-morbidity and low-mortality rates. However, postoperative complications have been reported. We report the case of a 40-year-old lady who suffered a fatal brain stem hemorrhage after burr hole drainage for unilateral chronic SDH. Rapid decompression or sudden increase in cerebral blood flow were the probable factors for her brainstem bleed. Therefore, a slow rate of evacuation of CSDHs and maintenance of a correct blood pressure perioperatively are recommended to prevent serious complications.

Introduction

Chronic subdural hematoma (CSDH) is a frequently encountered neurosurgical condition, especially in the elderly, with an incidence of 50 out of 100,000 and mortality of 0.5 to 4%.1,2 Burr hole drainage is the surgical modality of choice for the evacuation of CSDH. This technique is safe and easy to perform.3 However, postoperative complications, including cerebral edema, hematoma recurrence, subdural empyema, tension pneumocephalus, and intracranial hemorrhage at other sites, have been reported with variable frequencies.4,5 Brainstem bleeding secondary to this surgery is extremely rare, as so far only seven cases have been reported in the literature.6-12

Case Description

A 40-year-old lady with no known comorbidities presented to us with progressive worsening of her sensorium for a duration of 1 day. She had accidentally hit her head with a wall approximately 2 weeks prior to her presentation. On neurological examination, she had a Glasgow coma scale (GCS) score of 9 with left anisocoria. CT scan head (∼Fig. 1) showed a left 1.2 cm thick frontoparietal subdural hematoma (SDH) with mass effect and midline shift of 1 cm. She underwent burr hole drainage of the hematoma with a subdural drain. She improved to a GCS score of 15 over a couple of hours and her anisocoria also settled. Two hours after the procedure, she developed a sudden drop in GCS from 15 to 4, with pupils bilaterally dilated and fixed. Check CT was done immediately, and it demonstrated evacuation of the SDH with specks of pneumocephalus and brainstem hemorrhage (∼Fig. 2). The patient was intubated and ventilated; however, she remained comatose and died after 2 days.

Discussion

CSDH is a frequently encountered neurosurgical condition, especially in the elderly with a mortality rate of 0.5 to 4%. The highest incidence is in the fifth and sixth decades. CSDH is most commonly seen in men than women and the higher numbers in males is attributed to the males being more active than females. Headache is the most common presenting complaint.1-5 CSDHs are usually characterized by a history of head trauma, which may even go unnoticed.1-2 Some cases are secondary to defective coagulation, alcohol abuse, post-lumbar puncture, etc. CSDH should be suspected in a patient who presents with an unusually persistent headache after spinal anesthesia or lumbar puncture. Anticoagulant and
antiplatelet drugs have a significant association with an increased risk of CSDH.\(^{6,7}\)

The principal mechanism causing postoperative intracerebral hemorrhage is thought to be a sudden increase in cerebral blood flow combined with defective vascular autoregulation. But, the pathophysiology of brainstem hemorrhage following intracranial hematoma decompression is still not clear, since brain stem hemorrhage is often the cause of sudden death, so hemodynamic changes are difficult to study. It is suggested that the brainstem hemorrhage is likely due to damaged vessels caused by increased intracranial pressure (ICP).\(^{8,10,11,14}\) Rapid alleviation of increased ICP, under conditions of elevated blood pressure, could disrupt the small injured vessels, invariably resulting in brainstem hemorrhage. Because of the mass effect caused by CSDH, the blood vessels near the brainstem get stretched and distorted. The sudden decompression tears the blood vessels surrounding the brainstem, precipitating hemorrhage.\(^{15}\)

Physiological aging of the cerebral vascular tree is associated with poor tolerance of sudden variations in cerebral blood flow. In the elderly, the increased fragility of the small blood vessels might not be able to sustain the rapid changes in the brainstem blood flow during decompression of the SDH. Other factors responsible for brainstem hemorrhage, such as vascular malformations, bleeding tendency, and perioperative hypertension, are also some incriminating factors.\(^{12-16}\)

To the best of our knowledge, so far only seven cases (\(\quad\)Table 1)\(^{6-12}\) of brainstem hemorrhage, as a complication of surgery for CSDH, have been reported. Out of seven patients,
only one patient survived. Brainstem hematoma was diagnosed in the surviving patient, as he presented with gait disturbance. We also lost our patient. In our case, the most likely explanation could be rapid decompression with tearing of perforators to the brainstem.

Conclusion
Brainstem hematoma following CSDH evacuation is a very rare complication. Elderly age with a history of chronic hypertension are considered risk factors. Slow decompression and maintenance of a normal blood pressure perioperatively may prevent the occurrence of these complications.
