Metronomic Chemotherapy for Metastatic Breast Cancer – a Systematic Review of the Literature

Die metronomische Chemotherapie bei der Behandlung von metastasierendem Mammakarzinom – eine systematische Literaturrecherche

Abstract

Conventional chemotherapy is generally administered in high doses followed by a treatment-free period to give the body needful time to recover. This “maximum tolerated dose” approach results in high response rates. However, long periods between therapy cycles can lead to development of resistance mechanisms and consequently disease progression. One of the most interesting alternative strategies is metronomic chemotherapy. This concept relies on the continuous administration of chemotherapy at low doses and aims at targeting endothelial cells in the tumor bed as well. Recently, metronomic chemotherapy has been incorporated into the recommendations issued by the German AGO expert panel (www.ago-online.de). A systematic review of PubMed/Medline, ClinicalTrials.gov, the European Clinical Trials Database (EudraCT) and the Cochrane Database was conducted. In the present review, we discuss the current evidence on metronomic chemotherapy in metastatic breast cancer.

Zusammenfassung

**Introduction**

The schedule of conventional cytostatic treatment is based on the “maximum tolerated dose” (MTD) approach where high doses of a chemotherapeutic agent are given at 2–4 week intervals and target rapidly dividing cells. Since chemotherapy does not specifically eliminate cancer cells, but rather disrupts the process of cell division, normal non-cancerous cells that proliferate at a high rate are damaged as well, leading to typical side effects, such as hair loss, bone marrow suppression and mucositis. On the other hand, the long breaks between therapy cycles can allow tumor cells to recover and develop resistance, consequently resulting in disease progression. In the last two decades, alternative strategies have been explored in order to maximize treatment response while reducing toxicity. Most importantly, targeted therapy has become a major focus of oncological research and a number of drugs directed against tumor-associated target structures has been developed. Since their efficacy is not based on proliferation, these molecules specifically eliminate tumor cells, while leaving normal cells unaffected. Secondly, new approaches to chemotherapy itself have been proposed; among them, metronomic chemotherapy (MCT) is one of the most interesting ones [1]. MCT is based on the continuous administration of cytotoxic drugs at very low doses, thus reducing side effects and shortening the rest periods between treatments.

We performed a systematic review of published clinical studies on the use of metronomic therapy in metastatic breast cancer (BC) and searched the databases of PubMed/Medline, ClinicalTrials.gov, the European Clinical Trials Database (EudraCT) and the Cochrane Database for key terms related to metronomic chemotherapy and BC. Only articles published in English were considered. Case reports and reviews were excluded from our search. For trials with more than one publication, only the latest version was included in the analysis.

**The Concept of Metronomic Therapy**

**Anti-angiogenic effect**

Tumor growth depends not only on the aggressiveness of tumor cells themselves, but on the ability of endothelial cells in the tumor bed to develop new blood vessels as well. Therefore, one of the possible targets of oncologic therapy is the tumor’s vascular system. High doses of chemotherapy drugs require extended periods between treatment cycles to allow non-cancerous host cells to recover and resume their activity. During these therapy-free periods, endothelial cells in the tumor may also repair some of the damage induced by the chemotherapy and resume growth. This might contribute to the fact that tumor-associated neo-angiogenesis is not efficiently targeted by traditional chemotherapy. According to several experimental studies, low doses of cytotoxic drugs, administered without interruptions at shorter intervals, may bypass this hindrance and achieve tumor regression by elimination of endothelial cells involved in angiogenesis [2]. This continuous schedule is referred to as “metronomic” or “high time” chemotherapy [1]. In contrast to the “maximum tolerated dose” approach, the high-time chemotherapy aims at administering chemotherapeutic agents for the longest time possible at a given drug concentration (“high time for low dose”). In an animal-based study, Browder et al. showed that an “antiangiogenic” metronomic schedule of cyclophosphamide provided more sustained apoptosis of endothelial cells within the tumor bed, regardless of whether the tumor cells were drug resistant or not [3].

**Continuous cytotoxic effect**

Metronomic chemotherapy may also be seen as a variation of “dose-dense” therapy. The “maximum dose” approach generally requires breaks of two to four week duration to allow recovery from damaging side effects; reducing these interruptions is referred to as “dose density”. In early breast cancer, dose-dense chemotherapy, administered at frequent intervals (e.g. weekly), has been demonstrated to improve survival [4]. The weekly schedule has proved particularly beneficial when applied to taxanes. However, one major difference between dose-dense and metronomic approach is the cumulative dose, which is significantly higher in case of dose-dense therapy.

**Immunomodulatory effect**

Several cytotoxic drugs are able to induce immunogenic cell death. In animal-based models, metronomic administration of cyclophosphamide was shown to selectively reduce numbers of circulating regulatory T cells and thus curtail their immunosuppressive potential, resulting in a better control of the disease [5]. Recent studies suggested that antitumor immune responses obtained through metronomic treatment may evoke long-term immune memory leading to a rejection of tumor re-challenge in mouse models [6]. Results from immunodepletion studies suggest that tumor regression induced by metronomic therapy is mainly driven by its effects on the CD8+ T cells rather than NK cells [6]. Interestingly, even ultra-low noncytotoxic concentrations of chemotherapeutic agents, such as doxorubicin, methotrexate or paclitaxel can exercise immunomodulatory effects and directly up-regulate the ability of dendritic cells to present antigens for Ag-specific T cells in vitro [7].

**Review**

In the metastatic situation, therapy is mainly aimed at improving quality of life and controlling disease symptoms. In this context, metronomic chemotherapy may offer the possibility of prolonged treatment with less side effects (“high time, low dose”). A number of “older” cytotoxic drugs, such as cyclophosphamide (CTX), methotrexate (MTX), vinorelbine (VIN) and capecitabine (CAPE), have been tested in metronomic schedules. Some of the protocols include a combination of chemotherapy with antiangiogenic or endocrine therapy. The majority of ongoing trials aims at investigating low-dose metronomic capecitabine-based treatment. **Table 1** gives an overview of currently ongoing and completed clinical trials phase I–III in metastatic setting. Most trials on metronomic schedules focus on one of three settings:

1. metronomic therapy as an alternative to “conventional” chemotherapy with a more favorable safety profile;
2. metronomic therapy as a maintenance treatment after standard chemotherapy that would prolong the efficacy of conventional cytotoxic treatment;
3. metronomic chemotherapy as a combination partner for a targeted, antiangiogenic or immunologic agent.

randomized controlled trials were included in the meta-analysis. Nine patients treated with CAPE-based first-line therapy compared with CAPE-free therapy [10]. As expected, the safety profile differed between both groups with higher incidence of hematologic toxic effects comparable with other conventional chemotherapy drugs. While regular intake of a cytotoxic agent without long treatment-free intervals seems to follow the metronomic concept that calls for a schedule of daily capecitabine followed by one week of rest. At first, this metronomic treatment in the metastatic setting is capecitabine-based therapy. In contrast to the most extensively studied metronomic treatment in the second or higher line of treatment. [8] 

Metronomic Therapy as an Alternative to Conventionally Scheduled Chemotherapy

The most extensively studied metronomic treatment in the metastatic setting is capcitabine-based therapy. In contrast to other drugs, the standard administration schedule of capcitabine (CAPE) is an oral regimen, usually consisting of two weeks of daily capcitabine followed by one week of rest. At first, this schedule seems to follow the metronomic concept that calls for regular intake of a cytotoxic agent without long treatment-free breaks; however, the daily administered dose is high and side effects comparable with other conventional chemotherapy drugs. In contrast, metronomic regimens work with lower doses of capcitabine and aim at long-term therapy with less toxicity. While the threshold between “metronomic” and “standard” in case of capcitabine schedule has not been strictly defined yet, in the present review we considered regimens consisting of daily doses of < 2000 mg/m² as metronomic and ≥ 2000 mg/m² as standard non-metronomic approach. 

Capcitabine is most frequently used in the second or higher line of treatment [8]. According to the current ASCO guidelines, there are several effective agents appropriate for first-line chemotherapy and while the evidence is strongest for taxanes and anthracyclines, capcitabine is a valid option as well [9]. A recent meta-analysis showed improved PFS and response to treatment in patients treated with CAPE-based first-line therapy compared with CAPE-free therapy [10]. As expected, the safety profile differed between both groups with higher incidence of hematologic toxicity in the CAPE-free group and more gastrointestinal events and hand-foot syndrome under capcitabine-based treatment. Nine randomized controlled trials were included in the meta-analysis.

</table>

Of these, five investigated “standard”-dose capcitabine therapy (2000 mg/m²/d days 1–14 every three weeks in three trials, 2500 mg/m²/d in two trials). Patients in the remaining four trials were treated with daily doses < 2000 mg/m² [11–14]. Stockler et al. assigned 323 patients with advanced breast cancer to one of three regimens: standard capcitabine (1000 mg/m² twice daily for 14 of every 21 days), continuous metronomic capcitabine (650 mg/m² twice daily without breaks) and classical Bonadonna CMF regimen [12]. CAPE improved overall survival and was similarly active, less toxic, and more tolerable than CMF. No significant differences with respect to survival, tumor response and toxicity were observed between standard and metronomic CAPE schedules.

Other commonly administered metronomic regimens include cyclophosphamide (CTX) combined with either capcitabine or methotrexate (MXT) and vinorelbine(VIN)-based schedules. A direct comparison of these regimens with conventionally scheduled chemotherapy is problematic, since they were mostly tested in phase I/II non-randomized trials. The only phase III study was the Swiss SAKK 24/09 trial whose results were presented at the ASCO Annual Meeting 2014 [15]. 147 patients with HER2-negative metastatic breast cancer were randomized to first-line therapy with bevacizumab (BEV) with either paclitaxel or daily oral metronomic capcitabine and cyclophosphamide. Survival was similar in both arms; with regard to toxicity profiles, lower incidence of alopecia in metronomic arm was the only clinically and statistically significant difference. While this trial failed to meet its primary endpoint of a reduced rate of prespecified grade 3–5 adverse events of metronomic therapy, the authors concluded that the combination could be an active, convenient treatment in metastatic breast cancer.
Metronomic Therapy as a Maintenance Treatment After Standard Chemotherapy

Longer duration of first-line chemotherapy was shown to prolong progression-free and overall survival in a meta-analysis [16]. In earlier studies, continuous treatment until progression improved quality of life compared to intermittent chemotherapy administrated for a prespecified number of cycles [17, 18]. However, conventionally dosed chemotherapeutic agents, that follow the "maximum tolerated dose" approach, often require treatment interruption because of high toxicity. In this context, a switch to another, more tolerable regimen for a prolonged maintenance therapy might be an interesting option. The ongoing CAMELLIA trial aims at identifying the optimal schedule of capcitabine maintenance therapy after completion of first-line docetaxel/CAPE treatment (NCT01917279); the trial is currently recruiting. Smaller phase II studies investigated metronomic maintenance therapy after various schedules of conventional or combined chemotherapy. Ozdemir et al. treated 64 metastatic patients with cisplatin and low-dose capecitabine, followed by CAPE maintenance and reported acceptable toxicity and median overall survival of 17 months in this heavily pretreated group [19].

Metronomic Chemotherapy as a Combination Partner for Antiangiogenic Agents

Animal-based studies showed an improvement in efficacy of continuous metronomic chemotherapy by adding an antiangiogenic drug [2, 20]. This approach is based on the hypothesis that anti-vascular effects of a low-dose metronomic treatment might be enhanced through blockage of VEGF-mediates signals. Most studies investigating metronomic chemotherapy in combination with antiangiogenic agents focus on bevacizumab, the largest being the Dutch BOOG 2006–06 trial and the aforementioned SAKK 24/09 trial [11, 15, 21]. In the BOOG 2006–06 trial, 312 HER2-negative patients with locally relapsed or metastatic disease were assigned to first-line therapy with paclitaxel and bevacizumab ± oral CAPE (825 mg/m² twice daily on days 1–14), followed by maintenance treatment with bevacizumab alone or bevacizumab/capecitabine [11]. Patients receiving CAPE had significantly longer progression-free survival and better overall response rate than those in capcitabine-free arm, while overall survival remained similar in both groups.

Garcia-Saenz et al. reported on outcomes of 22 patients with pretreated metastatic BC who received metronomic oral cyclophosphamide, i.v. methotrexate and bevacizumab [21]. The treatment was well tolerated and yielded a clinical benefit rate of 64% and median PFS of 7.5 months. Dellapasqua combined another metronomic regimen (CTX/CAPE) with bevacizumab and reported similarly high clinical benefit rate (68%) [22]; further, response to treatment was correlated to levels of circulating endothelial cells (CEC) before start of treatment. Patients with elevated CEC numbers achieved better response than patients with lower CEC level. Whether CECs, the assumed biomarker of vascular damage, might serve as a predictor of response to antiangiogenic therapy remains to be clarified in future studies [23]. An attempt to enhance the efficacy of the triple-therapy with CTX/CAPE/BEV was undertaken in a subsequent phase II trial by Montagna et al. [24]. 24 patients with metastatic HER2-negative BC with low or negative expression of hormone receptors were treated with a combination of metronomic chemotherapy, bevacizumab and an EGFR-inhibitor erlotinib; the overall clinical benefit rate was 75% and median time to progression 43 weeks. In contrast, discouraging results were provided by a phase II trial investigating the combination of metronomic VIN and BEV [25]. Among 13 patients included, only one achieved partial response and the trial was closed prematurely due to lack of efficacy. Another drug with antiangiogenic properties is thalidomide; besides immunomodulating activity, thalidomide was shown to inhibit VEGF-induced angiogenesis in animal models [26]. Colleoni et al. aimed at testing this hypothesis and treated 171 patients with a metronomic regimen of CTX/MTX ± oral thalidomide in a phase II randomized trial [27]. Addition of thalidomide resulted in a significantly higher toxicity but did not increase response rates. Mayer et al. investigated the efficacy of vandetanib, another drug with antiangiogenic properties, in combination with metronomic chemotherapy in a small phase I trial [28]. Vandetanib is an oral inhibitor of VEGF-receptor and has been approved for treatment of medullary thyroid carcinoma. 23 patients with metastatic breast cancer received metronomic CTX/MTX chemotherapy and vandetanib in 3 dose-escalation cohorts; the clinical benefit rate was 25% [28].

Metronomic Chemotherapy as a Combination Partner for Targeted Therapy

Patients with HER2-overexpressing metastatic disease benefit from HER2-targeted agents that are usually combined, at least initially, with a chemotherapy. Current standard of care for first-line therapy of HER2-positive MBC is conventionally dosed docetaxel with dual antibody blockade trastuzumab/pertuzumab [29]. Another anti-HER drug, T-DM1, is becoming the standard for second-line treatment at progression [30]. HER2-directed agents administered with metronomic therapy have been studied in phase II and III trials and remain valid options for later-line treatment. The combination of trastuzumab with dual metronomic regimen, CTX/MTX, has been evaluated in a phase II trial [31]. Besides already approved anti-HER2 agents, such as trastuzumab and lapatinib, the possibility of combining metronomic chemotherapy with novel targeted drugs has been explored. In a phase I/II dose-escalation trial, 72 trastuzumab-pre-treated patients received metronomic capecitabine and neratinib, a dual inhibitor of the HER2 and EGFR kinases [32]. This treatment resulted in a median PFS of 40 weeks in patients with no prior lapatinib exposure and 36 weeks in patients previously treated with lapatinib.

Metronomic Chemotherapy as a Combination Partner for Endocrine Therapy

The optimal sequence of chemotherapy and endocrine treatment has not been fully clarified and while some studies showed a slight significant improvement in response rates of concurrent chemo-endocrine therapy, others reported higher incidence of adverse events in case of simultaneous treatment [33, 34]. In animal models, combined chemo-endocrine therapy showed the supra-additive antitumor activity compared to either monotherapy [35]. In clinical practice, conventionally scheduled, "maximum tolerated dose" cytotoxic treatment is generally administered without simultaneous anti-hormonal agents. In contrast, low-dose continuous chemotherapy may be given for prolonged...
periods without causing serious side effects and several authors explored the possibility of combining metronomic chemotherapy with endocrine treatment. Two trials examined fulvestrant and one focussed on megestrol acetate. In a phase II trial, 41 patients with hormone receptor positive and HER2-negative metastatic BC were treated with fulvestrant and capcitabine [36]. All patients were previously treated with at least one line of endocrine therapy in the metastatic setting. Combination therapy was well tolerated and led to a median PFS of 15 months and OS of 28.6 months. In another study, simultaneous therapy with fulvestrant and another metronomic regimen (CTX/MTX) yielded clinical benefit rate of 56% [37]. Licchetta et al. reported on a combination of metronomic cyclophosphamide with megestrol acetate in 29 pretreated metastatic patients; the combination was well-tolerated and active with mean time to progression of 7.4 months and mean OS of 13.4 months [38].

**Metronomic Chemotherapy as a Combination Partner for Immunomodulatory Therapy**

In the last two decades, the role of immunomodulating agents in oncological therapy has gained considerable interest. This approach is based on the hypothesis that immune microenvironment of the tumor can be altered and become thus more hostile to cancer cells [39]. Cyclophosphamide is a strong inhibitor of FoxP3+ regulatory T-cells, leading to re-activation of tumoranti-gen-specific immune-reactions by T- and B-cells. In a small phase II study 12 metastatic BC patients were treated with cyclophosphamide 50 mg per day. Treg level dropped down by 40% while T-effector cell level increased. Patients that responded to the immunomodulatory treatment showed a prolonged overall survival [40].

One of the currently evaluated options are vaccines designed to stimulate specific immunity to cancer antigens; several clinical trials testing therapeutic vaccines in metastatic breast cancer are ongoing. Whether the efficacy of vaccination can be increased by simultaneous low-dose chemotherapy remains to be clarified. Soriano et al. treated 21 patients with progression of metastatic disease with dual metronomic chemotherapy (CTX/MTX) combined with subcutaneous injections of 1E10 anti-idiotype vaccine, followed by monthly re-immunizations and reported a median time to progression of 9.8 months and OS of 12.9 months [41]. Wang et al. focussed on young patients with aggressive triple-negative disease who were previously treated with anthracyclines and taxanes; after salvage polychemotherapy with cyclophosphamide/thiotepa/carboplatin 23 patients received infusions with DC/CIKs (dendritic cells-activated cytokine-induced killer cells), followed by maintenance metronomic chemotherapy with oral cyclophosphamide [42]. The median PFS and OS were 13.5 and 15.2 months, respectively; a high rate of hematological toxicity was reported but there were no treatment-related deaths. Celecoxib, a non-steroidal anti-inflammatory agent with immunomodulatory properties has been tested in combination with docetaxel and metronomic CAPE as well [43].

**Conclusions**

Metronomic chemotherapy has been proposed as an alternative to conventionally scheduled cytotoxic treatment following the “maximum tolerated dose” rule. In the metronomic concept the notion of “the higher the dose, the better” has been replaced by “high time, low dose”, with the aim of administering systemic therapy continuously for as long as possible with minimal side effects. Metronomic chemotherapy has gained considerable interest in the field of pediatric oncology and various adult solid tumors. In breast cancer, a number of clinical trials investigated the efficacy and feasibility of this therapeutic approach. Metronomic chemotherapy is a valid option in metastatic setting. Its use has been incorporated into the recently updated guidelines issued by the German expert panel “AGO Breast Committee”: metronomic therapy is recommended for patients with hormone receptor positive, HER2-negative metastatic breast cancer treated previously with taxanes and anthracyclines (wwwAGO-online.de).
