Abstract
Understanding the fundamental principles of tooth movement could reduce the duration of treatment and achieve a stable outcome, resulting in patient satisfaction. Hyperbaric oxygen therapy was a modality in which a patient inhaled 100% \( \text{O}_2 \) while subjected to high atmospheric pressure. Hyperbaric oxygen therapy facilitated the supply of oxygen to the human body's organs and tissues and served a variety of applications, including patient care and wound treatment. This review article aimed to describe animal studies of the potential effects of hyperbaric oxygen therapy in orthodontic therapy. It was conducted using a systematic literature review method, including searching PubMed and Google Scholar for publications relevant to the research topics. The search was filtered to include only research on orthodontic treatment and hyperbaric oxygen therapy and was published in any year. Articles that did not specify biological components of orthodontic tooth movement (OTM) were excluded. The Preferred Reporting Items identified the papers for the Systematic Reviews and Meta-Analyses (PRISMA) strategy, which resulted in the selection of 11 publications. Hyperbaric oxygen therapy affected parameters of biomarkers representing the clinical, molecular, and cellular biology of bone formation and resorption in periodontal tissues in responding to orthodontic physical forces, including alkaline phosphatase, collagen synthesis, osteoblast, osteoclast, osteocyte, type I collagen, vascular endothelial growth factor, osteocalcin, fibroblast, matrix metalloproteinase-8, transforming growth factor-\( \beta \), partial pressure of oxygen, partial pressure of carbon dioxide, trabecular bone density, and tooth mobility. Hyperbaric oxygen therapy induced an inflammatory response to follow OTM events during active orthodontic

therapy. Hyperbaric oxygen therapy might play a role in the tissue healing process during passive treatment. Nonetheless, additional research should be conducted to establish the efficacy of hyperbaric oxygen therapy in orthodontics.

Introduction

Orthodontic treatment is predicated on the idea that applying pressure on a tooth would induce it to migrate as the surrounding bone reformed. The bone is deliberately removed from some areas and added to the others. The tooth migrated through the bone, bringing the periodontal ligament (PDL) with it. Since the PDL mediated the bony reaction, tooth movement was primarily a PDL event. Understanding the basic concept of tooth movement might help shorten treatment times, stabilize the result, and increase patient satisfaction. An optimum orthodontic force maximizes cellular responsiveness and tissue stability, whereas an unfavorable one might trigger adverse tissue reactions. Tooth movement is induced by an aseptic inflammation associated with histological findings of necrotic/hyaline sites, vasodilation, and leukocyte migration from blood vessels. Undifferentiated mesenchymal cells and their progeny in fibroblasts and osteoblasts accounted for most of the PDL cellular components. During normal function, the ligament’s collagen was constantly rebuilt and regenerated. The same cells could act as fibroblasts and fibroblasts, producing new collagenous matrix components and degrading previously made collagen.

Hyperbaric oxygen therapy (HBOT) is a procedure in which a patient inhales 100% oxygen while being subjected to an increased atmospheric pressure up to 2 to 3 atmospheres absolute for 1.5 to 2 hours, one to three times per day, depending on the indication. The intracellular genesis of reactive oxygen and nitrogen species was a critical mechanism for HBOT. The role of reactive substances such as oxygen and nitrogen in this process is revealed through cell signaling transduction cascades. Nitrogen and reactive oxygen species combined cause cell damage, resulting in nitrative stress. HBOT has facilitated the delivery of oxygen to the tissues; as a result, wound healing might be improved, and patients’ recovery times were reduced. HBOT has been used for several purposes, such as patient and wound care. HBOT facilitated the supply of oxygen to the biological body’s cells. While HBOT has a variety of applications in dental care, it is most frequently utilized to prevent complications during radiation therapy. This review aimed to discuss the potential effects of HBOT in orthodontic treatment in animal studies.

Methods

Research/Review Question

The first approach in undertaking a complete systematic review was to characterize the problem through an organized study. Patient/Population, Intervention, Comparison, and Outcome format was one method for transforming a clinical trial into a review question. The research question for this study referred to the following: P (Patient/population): Patients under orthodontic treatment, I (Intervention): Orthodontics treatment with HBOT, C (Comparison): Orthodontic treatment without HBOT, and O (Outcome): Efficacy of HBOT as an adjunctive method in orthodontic treatment.

Inclusion/Exclusion Criteria

Dhammi and Haq noted that it was necessary to specify the studies to be included and those omitted while doing a systematic review. Generally, studies with a significant level of evidence were required. However, if the subject of the review was insufficient, it was prudent to incorporate research at a lower level. Additionally, the language in which the paper was written was critical. Although restricting the systematic review to articles written in English would influence the result, it might be desirable if translation services and other resources were limited. Furthermore, it was necessary to note the relevant research date of publication. Finally, it should be determined if just human research or human and animal studies will be included.

All relevant articles were included because of a lack of research on this issue. Both human and animal studies were included and categorized as gray articles (academic papers, including theses and dissertations, research and committee reports, government reports, conference papers, and ongoing research). All remaining publications’ titles and abstracts were carefully reviewed to rule out those not meeting the inclusion criteria. Articles that did not examine the use of HBOT in orthodontic treatment were excluded.

Systematic Literature Search

To discover papers relevant to the issue of this systematic review, a comprehensive search of the PubMed and Google Scholar databases was done. First, as many significant themes as possibly linked with this review topic should be identified using keywords/Medical Subject Headings terms ("orthodontic treatment") and ("hyperbaric oxygen therapy"). Then, these keywords were merged using the Boolean operator (AND). Finally, no filters were applied to the PubMed and Google Scholar searches due to a lack of relevant evidence.

The papers obtained in this search were examined individually, using the manuscripts’ title, abstract, and full text to determine their eligibility. The references listed in the included papers were further reviewed to see whether any more published articles were overlooked during the database search. The flowchart in Fig. 1 depicts the study’s exact flow and several Preferred Reporting Items in Systematic Reviews and Meta-Analysis items.
was conducted. For example, in vitro true experimental study method was used in one study, while 10 other studies were based on in vivo true experimental. The quality of evidence of the studies was analyzed by three independent raters (not including the authors). As indicated in Table 1, the NIH quality assessment tool determined that eight papers were of excellent quality, two articles were of fair quality, and one item was of low quality or had a high potential for bias.

**Discussion**

OTM biomarkers are those associated with inflammation, bone resorption, cell death, bone deposition, and mineralization. They are interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor (TNF)-β, colony, macrophage colony-stimulating factor (M-CSF), granulocyte-CSF, granulocyte-macrophage-CSF, vascular endothelial growth factor (VEGF), prostaglandin E, calcitonin gene-related peptide, substance P, RANK, RANKL, G, aspartate aminotransferase, and lactate dehydrogenase, osteoprotegerin, as well as alkaline phosphatase (AP). These biomarkers provide insight into osteogenesis and osteoclast genesis molecular and cellular biology in response to orthodontic mechanical pressures. In addition, parameters or biomarkers used to analyze in the included articles comprised AP), collagen synthesis, osteoblast, osteoclast, osteocyte, type I collagen, VEGF, osteocalcin, fibroblast, matrix metalloproteinase-8 (MMP-8), transforming growth factor (TGF)-β, partial pressure of oxygen (pO2), partial pressure of carbon dioxide (pCO2), trabecular bone density, teeth mobility, PDL width, number of blood vessels, and TNF receptor associated factor 6 (TRAF-6). From this perspective, it can be concluded that some other biomarkers involved in the orthodontic biological process might be further investigated.

Only two of those available articles comprehensively discussed the effect of HBOT on OTM in the pressure-tension terminology. HBOT promoted VEGF in the tension site but not in the pressure site. Brahmana et al concluded that HBOT increased TGF-β in the tension site and MMP-8 in the pressure site. Those events in the tension site represented osteogenesis, while those in the pressure site represented osteoclastogenesis. The remaining articles focused on one aspect of OTM terminology (compressive or tensile) or the general aspect.

OTM was a process that incorporated pathologic and physiological responses to environmental pressures. As a result, relevant inflammatory mechanisms had to be taken into account. The applied forces caused instantaneous strains in the tooth-supporting tissues, which might be classified as compressive or tensile. Blood was squeezed out and vessels collapsed in the compressed periodontal membrane, dilating on the tension side. Although bone resorbed upon regeneration of the collapsed vasculature, dilation of blood vessels on the tension side appeared to stimulate subsequent bone deposition. The pressure-tension concept could be useful in distinguishing the various mechanisms associated with OTM.

(Continued)
Greater orthodontic forces resulted in necrosis and hyalination, and tooth movement could only be accomplished at the expense of bone resorption and a hypoxic periodontal membrane. On the other hand, lesser orthodontic forces were associated with minimal necrosis and hyalination. Compression of the periodontal membrane and adjacent alveolar bone by orthodontic forces might result in apoptosis, hyalinization, and eventual hypoxia. Tunçay et al discovered that low ambient oxygen tension increased cell growth while decreasing AP activity collagen synthesis, whereas HBOT-induced hyperoxia suppressed cell growth while increasing AP activity collagen synthesis.

The predominant mediators of neoangiogenesis were hypoxia-inducible factor-1 and VEGF. Periodontal structures, which experienced significant remodeling during OTM, seemed to be susceptible to changes in O₂ supply. Hypoxia, caused by a vascular impairment, had been identified as a considerable constraint in wound healing. Therefore, supplemental oxygenation to treat hypoxia might have a significant beneficial effect on wound healing. Along with its nutritional and antibacterial properties, O₂ might promote angiogenesis, cell motility, and extracellular matrix synthesis.

Angiogenesis plays a vital role in the early stages of healing. VEGF was a potent angiogenic promoter at the wound site. In vivo, oxygen boosted VEGF protein expression in wounds and VEGF messenger ribonucleic acid expression in endothelial cells and macrophages. Collagen deposition was critical for wound healing because it served as the revascularization and tissue remodeling matrix. O₂ was necessary for several posttranslational phases in the synthesis of collagen. Improved wound oxygenation increased collagen synthesis and elastic modulus, with the most significant effect happening when wound oxygenation was increased above physiological levels by adding more O₂.

The potential use of HBOT in orthodontic treatment seemed evident and supported by significant scientific evidence. However, HBOT had significant potential effects in orthodontic therapy. Almost fewer have been studied in orthodontic patients. Among the included articles, only one article used humans in the study. Salah and Eid used 20 orthodontic patients to evaluate the effect of HBOT on tooth mobility during orthodontic treatment. The other studies used animals (Sprague-Dawley rats, dogs, guinea pigs, and Cavia cobaya). HBOT's effects got more investigated during inactive phase of orthodontic treatment. Only two studies described using HBOT in the passive phase to prevent orthodontic relapse. Salah and Eid demonstrated that HBOT might be useful in reducing tooth mobility during and after orthodontic treatment. According to Prayogo et al, the interaction of HBOT and propolis gel affected the PDL width and the number of fibroblasts responsible for reducing orthodontic relapse risk.

The periodontium comprises gingiva, PDL, alveolar bone, and cementum surrounding the tooth root. Compared with the other components of the periodontium, gingival tissue was not investigated in the included articles to highlight the comprehensive interrelationship between orthodontics, periodontics, and HBOT. Unlike the bone and periodontal

membrane, the gingiva did not remodel promptly in response to orthodontic mechanical pressures; gingival collagen fibers were compressed and retracted for a lengthy time. In the compressed gingiva, the number of elastic fibers increased considerably. Compressed gingiva resembled compressed rubber, which would revert to its original proportions once the compression force was removed. Orthodontic relapse occurred due to the prolonged elastic deformation of gingival fibers, which impaired the surrounding teeth. To maintain appropriate tissue stability and avoid orthodontic relapse, an equilibrium between collagen catabolic and anabolic gingival fibers was necessary. HBOT offers some potential effects to be investigated further in preventing orthodontic relapse.

Conclusion

To summarize, the potential for HBOT use in orthodontic treatment appears reasonably obvious and is supported by substantial scientific evidence. HBOT effects parameters or biomarkers that reflect the clinical, molecular, and cellular biology of osteogenesis and osteoclastogenesis in periodontal tissues in response to orthodontic mechanical pressure, such as AP, collagen synthesis, osteoblast, osteoclast, osteocyte, type I collagen, VEGF, osteocalcin, fibroblast, MMP-8, TGF-β, pO2, pCO2, trabecular bone density, teeth mobility, PDL width, number of blood vessels, and TRAF-6. HBOT initiates an inflammatory response followed by OTM events during active orthodontic treatment. However, HBOT also plays a role in the tissue healing process during passive treatment. Nonetheless, additional research should be conducted to establish the efficacy of HBOT in orthodontic treatment in human studies.

Authors’ Contributions
All authors in this study admit to their involvement in the manuscript’s creation stages. Y.M.A. conceived the ideas. Y.M.A., A.M.M., E.M., and G.W. gathered and processed data. Finally, Y.M.A. and A.S.S. helped finalize the manuscript.
