Abstract

Pulmonary embolism (PE) is one of the most common etiologies of cardiovascular mortality. It could be linked to several risk factors including advanced age. The pathogenesis of PE is dictated by the Virchow's triad that includes venous stasis, endothelial injury, and a hypercoagulable state. The diagnosis of PE is difficult and is often missed due to the nonspecific symptomatology. Hypoxia is common in the setting of PE, and the degree of respiratory compromise is multifactorial and influenced by underlying cardiac function, clot location, and ability to compensate with respiratory mechanics. Right ventricular dysfunction/failure is the more profound cardiovascular impact of acute PE and occurs due to sudden increase in afterload. This is also the primary cause of death in PE. High clinical suspicion is required in those with risk factors and presenting signs or symptoms of venous thromboembolic disease, with validated clinical risk scores such as the Wells, Geneva, and pulmonary embolism rule out criteria in estimating the likelihood for PE. Advancement in capture time and wider availability of computed tomographic pulmonary angiography and D-dimer testing have further facilitated the rapid evaluation and diagnosis of suspected PE. Treatment is dependent on clinical presentation and initially involves providing adequate oxygenation and stabilizing hemodynamics. Anticoagulant therapy is indicated for the treatment of PE. Treatment is guided by presence or absence of shock and ranges from therapeutic anticoagulation to pharmacologic versus mechanical thrombectomy. The prognosis of patients can vary considerably depending on the cardiac and pulmonary status of patient and the size of the embolus.

- ▶ deep venous thrombosis

Venous thromboembolic (VTE) disease presents as a major burden to health care and affects approximately 10 million cases per year.^{1,2,3,4} In clinical practice, it is encountered as either deep vein thrombosis (DVT) and/or pulmonary embolism (PE) and is thought to affect as many as 900,000 individuals in the United States each year and associated with substantial morbidity and mortality.

It is estimated that there are approximately 10 million new cases of VTE in the world on an annual basis. In the United States, it is estimated that the incidence of diagnosed VTE is 117 per 100,000, but this number may be an underestimation as most cases are frequently not diagnosed or only discovered on autopsy.¹

PE is thought to develop in approximately 10% of patients with acute DVT and it can lead to approximately 10% of

Table 1 Virchow's triad

Venous stasis
Endothelial injury
Hypercoagulable state

hospital deaths. It is also a known fact that most patients (up to 75%) with PE are asymptomatic. It is further thought that about one-third of the hospitalized patients in the United States are at high risk of developing VTE and about 100,000 deaths are related to this disease per year.^{2,3,4}

The annual incidence of venous thrombosis, including DVT and PE, is estimated to occur in 1 out of 1,000 adults. Rates increase significantly after age 45 years and are higher in males than in females.³

In this article, we discuss the pathophysiology of PE and management of this condition.

Pathophysiology

The pathogenesis of PE is dictated by the Virchow's triad like other intravascular thrombi and is a combination of venous stasis, endothelial injury, and a hypercoagulable state (→ **Table 1**). The etiology/risk factors leading to culmination of the triad can be inherited or acquired (→ **Table 2**).

Table 2 Risk factors for pulmonary emboli

Acquired
Immobilization
Major trauma or surgery within 4 weeks
Active cancer (treatment within 6 months or palliative therapy)
Prior history of thromboembolism
Reduced cardiac output/Heart Failure
Obesity
Pregnancy, early puerperium
Estrogen/ oral contraceptives
Indwelling catheters
Antiphospholipid antibodies
Thrombocytosis
Postsplenectomy
Heparin induced thrombocytopenia
Primary hypercoagulable states/ Thrombophilia
Deficiency of antithrombin III, protein C or S
Resistance to activated protein C (factor V Leiden)
Elevated plasminogen activator inhibitor
Hyperhomocysteinemia
High plasma concentration of factor VIII
Prothrombin gene mutation (G20210A polymorphism)

Most PEs originate from the deep veins of lower extremity. The common sites of thrombus formation are in the calf veins followed by femoropopliteal veins and finally the iliac veins. A blood clot dislodges from the vessel wall and travels into the pulmonary system, eventually lodging in the pulmonary arteries. When large pulmonary vessels are involved, it could cause severe hemodynamic instability including right ventricular (RV) pressure overload, RV failure, and eventually death (→ **Fig. 1**).

Hypoxia is common in the setting of PE, and the degree of respiratory compromise is multifactorial and influenced by underlying cardiac function, clot location, and ability to compensate with respiratory mechanics.^{5,6} Embolus size does not correlate with severity of hypoxia.⁷ There are multiple mechanisms that eventually lead to hypoxia, including (1) ventilation perfusion mismatch causing redistribution of perfusion to nonoccluded areas, leading to regional lower perfusion and hence skewing the V/Q ratio; (2) regional bronchoconstriction leading to reduced ventilation atelectasis, which further causes intrapulmonary shunting leading to hypoxia; (3) reduced cardiac output leading to reduced central venous oxygen pressures and hence hypoxia; (4) increase in right atrial pressure that can open the patent foramen ovale, thereby leading to intracardiac right-to-left shunting and hence hypoxia.^{5,8,9,10,11,12}

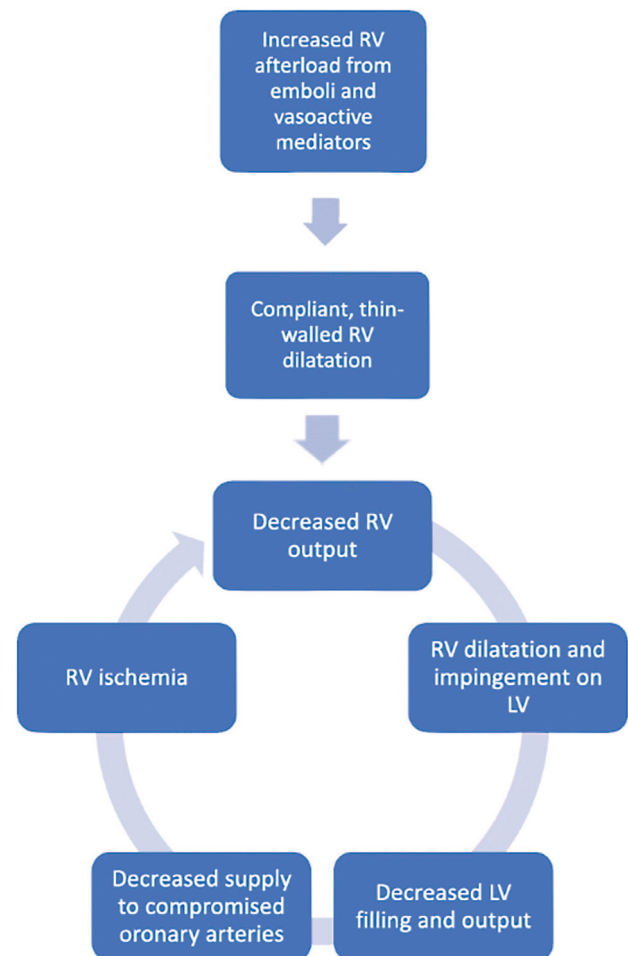

**Fig. 1** Pathophysiology of right ventricular failure. LV, left ventricle; RV, right ventricle.

Table 3 Wells criteria and modified Wells criteria: clinical assessment for pulmonary embolism

Clinical symptoms of DVT (leg swelling, pain with palpation)	3.0
Other diagnosis less likely than PE	3.0
Heart rate >100	1.5
Immobilization (≥ 3 days) or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Hemoptysis	1.0
Malignancy	1.0
Probability	Score
Traditional clinical probability assessment (Wells criteria)	
High	>6.0
Moderate	2.0–6.0
Low	<2.0
Simplified clinical probability assessment (modified Wells criteria)	
PE likely	>4.0
PE unlikely	≤ 4.0

Abbreviations: DVT, deep vein thrombosis; PE, pulmonary embolism.

RV dysfunction/failure is the more profound cardiovascular impact of acute PE and occurs due to sudden increase in afterload. This is also the primary cause of death in PE. At baseline, the RV is a thin-walled chamber that pumps against a low-pressure and low-resistance pulmonary vasculature. Increase in afterload is due to mechanical obstruction of the pulmonary vasculature that impedes blood flow and release of vasoconstrictors like TXA₂. (Thromboxane) due to hypoxia.^{6,13,14,15} TXA₂ is a hormone of the prostacyclin type released from blood platelets. It induces platelet aggregation and produces local vasoconstriction. This increase in afterload and pulmonary vascular resistance stretches the RV, increases wall tension, and causes compensatory increase in chronotropy and inotropy to maintain the Frank-Starling mechanism and adequate cardiac function at the expense of pulmonary hypertension.^{16,17,18} The compensation reaches a tipping point, beyond which the increase in PA pressures cannot generate further RV dilation, causing RV failure. Increased myocardial wall tension and transmural pressure cause ischemia by impeding coronary flow. This, in the presence of hypoxia and increased afterload, precipitates a vicious cycle of worsening myocardial ischemia, reduced RV contractility, reduced cardiac output, and eventual RV failure. Progressive RV dilation will also exacerbate previously nascent tricuspid regurgitation that can then trigger arrhythmias and hence worse cardiac performance.^{19,20} There is also an inflammatory component, as evidenced by the influx of granulocytes and monocytes that suggests myocarditis.^{21,22}

Diagnostic Evaluation

Thorough history and identification of risk factors and physical exam are essential in guiding the appropriate diagnostic evaluations. Preliminary evaluation would in-

clude 12-lead electrocardiogram, on which the most common findings are sinus tachycardia (44%), RV strain pattern/T-wave inversions (34%), right axis deviation (16%), and right bundle branch block (18%).²³

Chest X-ray features of acute PE include enlarged pulmonary artery (Fleischner sign), regional oligemia (Westermark sign), and Hampton hump (wedge-shaped distal infarct) that have high specificity, but very low sensitivity.

Multiple risk scores have been developed to quantify the pre-test probability of PE and help guide the diagnostic process and triage them accordingly. The Wells score and modified Wells score use seven clinical indicators to stratify in to “PE likely” and “PE unlikely” groups (►Table 3). The Geneva score relies only on objective data to stratify in to low-, intermediate-, and high-risk categories (►Table 4). The pulmonary embolism rule out criteria rule can be used in low-risk patients to avoid unnecessary diagnostics (►Table 5).

In clinically stable patients obtaining a D-dimer, a soluble fibrin degradation product, is typically the next diagnostic step. Due to the high diagnostic sensitivity (>95%) and negative predictive value, it is primarily used to help exclude PE when the levels are normal. D-dimer, however, has poor diagnostic specificity (41%), and when elevated, it can be due to other various conditions such as sepsis, trauma, cancer, surgery, other thrombosis, or disseminated intravascular coagulation, among others.²⁴

In patients with high clinical probability or abnormal D-dimer, computed tomography (CT) angiography of the pulmonary vasculature is the next diagnostic step (►Fig. 2) Advancements in imaging have reduced acquisition times to a few seconds, making it possible to get high-resolution images even in the presence of dyspnea. CT also provides assessment for other conditions in the differential diagnosis

Table 4 Modified Geneva score

Variables		Points
Risk factors	Age >65 years	1
	Previous deep venous thrombosis or pulmonary embolism	3
	Surgery under general anesthesia or fracture of the lower limbs within 1 month	2
	Active malignancy (solid or hematologic; currently active or cured within the last year)	2
Symptoms	Unilateral lower-limb pain	3
	Hemoptysis	2
Signs	Heart rate 75 to 94 beats per minute	3
	≥95 beats per minute	5
	Pain on lower limb deep venous palpation and unilateral edema	4
		Total points
Pre-test probability assessment	Low	0 to 3
	Intermediate	4 to 10
	High	≥ 11

Table 5 Pulmonary embolism rule out criteria (PERC rule)^a

Age <50 years
Heart rate <100 bpm
Oxyhemoglobin saturation ≥95%
No hemoptysis
No estrogen use
No prior DVT or PE
No unilateral leg swelling
No surgery/trauma requiring hospitalization within the prior 4 weeks

Abbreviations: DVT, deep venous thrombosis; PE, pulmonary embolus; bpm: beats per minute.

^aThis rule is only valid in patients with a low clinical probability of PE (gestalt estimate <15%). In patients with a low probability of PE who fulfill all eight criteria, the likelihood of PE is low and no further testing is required. All other patients should be considered for further testing with sensitive D-dimer or imaging.

of dyspnea and tachycardia like pneumonia, coronavirus disease 2019, and effusions.²⁵ If computed tomography angiography (CTA) is contraindicated (renal failure, allergy, pregnancy), ventilation perfusion scans can be utilized, which have a sensitivity and specificity of 85 and 93%, respectively.²⁶

Echocardiography can be helpful in assessing RV function and subsequent risk stratification since it is typically associated with worse outcomes. PE can also cause RV failure and cardiogenic shock due to obstruction and increased pulmonary vasoconstriction.²⁷

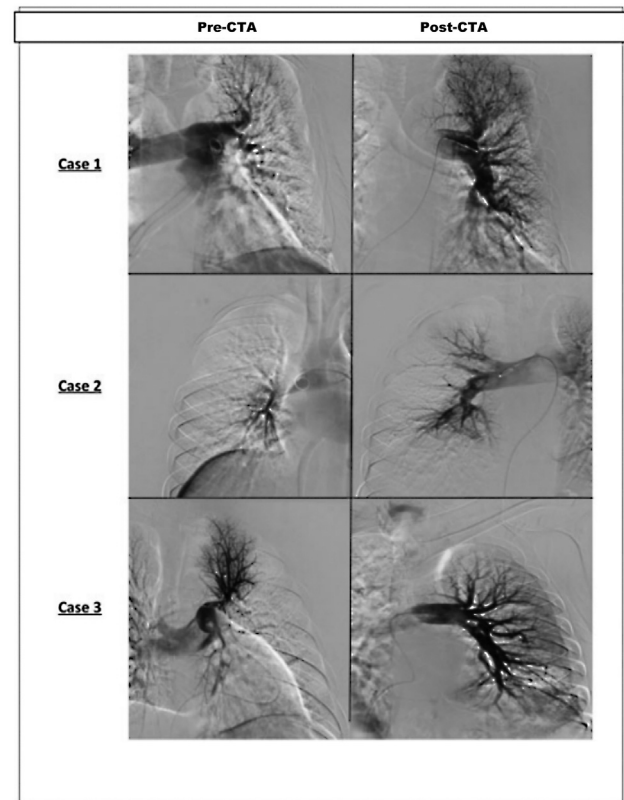

Fig. 2 Pre- and post-computed tomography angiography (CTA) images following thrombolysis showing significant improvement in pulmonary.

Treatment

PE can range from acute massive PE causing pulmonary infarction or could be secondary to small emboli that do

Table 6 Dosing of direct oral anticoagulants

Anticoagulant	Nonvalvular AF -stroke prophylaxis	VTE treatment	VTE primary prophylaxis
Dabigatran (Pradaxa)	150 mg twice daily	Parenteral anticoagulation for 5 to 10 days; then dabigatran 150 mg twice daily	110 mg for the first day, then 220 mg once daily
Apixaban (Eliquis)	5 mg twice daily	10 mg twice daily for 1 week, then 5 mg twice daily	2.5 mg twice daily
Edoxaban (Savaysa, Lixiana)	60 mg once daily	Parenteral anticoagulation for 5 to 10 days; then edoxaban 60 mg once daily	
Rivaroxaban (Xarelto)	20 mg once daily with the evening meal	15 mg twice daily with food for 3 weeks; then 20 mg once daily with food	10 mg once daily, with or without food

Abbreviations: AF, atrial fibrillation; VTE, venous thromboembolic.

not cause hemodynamic instability. Patients with PE can present with minor nonspecific symptoms like dyspnea, to symptoms of shock with systolic blood pressures less than 90 mm Hg or a decrease in systolic arterial pressure of at least 40 mm Hg for 15 minutes or more.

Treatment is dependent on clinical presentation and initially involves providing adequate oxygenation and stabilizing hemodynamics. Treatment of the PE per se is guided by presence or absence of shock.

Patients without shock are low risk and can be treated with anticoagulation, which is the mainstay of most PE treatments. Parenteral treatment can be started with heparin or enoxaparin and transitioned to warfarin for a goal international normalized ratio between 2 and 3. Direct-

acting oral anticoagulants, on the other hand, have quick onset of action and do not require bridging with parenteral anticoagulants²⁸ (► **Table 6**). Duration of anticoagulation is 3 to 6 months but is required lifelong if there is a recurrence of PE/DVT.²⁹

Thrombolytic therapy is reserved for patients with cardio-respiratory compromise/shock. It can also be used with severe right heart strain or RV failure. Thrombolytics cause clot-lysis, hence, resuming circulation and reducing RV strain. tPA, or tissue plasminogen activator, is the most commonly used thrombolytic and administered as a 100 mg infusion over 2 hours. For catheter-directed thrombolysis, tPA is infused at 0.5 to 2 mg/h for 2 to 15 hours. Contraindications for tPA are outlined in ► **Table 7**.

Table 7 Contraindications to fibrinolytic therapy

Absolute contraindications
Prior intracranial hemorrhage
Known structural cerebral vascular lesion
Known malignant intracranial neoplasm
Ischemic stroke within 3 months (excluding stroke within 3 hours ^a)
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed-head trauma or facial trauma within 3 months
Relative contraindications
History of chronic, severe, poorly controlled hypertension
Severe uncontrolled hypertension on presentation (SPB >180 mm Hg or DBP > 110 mm Hg)
History of ischemic stroke more than 3 months prior
Traumatic or prolonged (>10 minute) CPR or major surgery less than 3 weeks
Recent (within 2–4 weeks) internal bleeding
Noncompressible vascular punctures
Recent invasive procedure
For streptokinase/anistreplase—prior exposure (> 5 days ago) or prior allergic reaction to these agents
Pregnancy

(Continued)

Table 7 (Continued)

Active peptic ulcer
Pericarditis or pericardial fluid
Current use of anticoagulant (e.g., warfarin sodium) that has produced an elevated INR >1.7 or PT >15 seconds
Age >75 years
Diabetic retinopathy

Abbreviations: CPR, cardiopulmonary resuscitation; DBP, diastolic blood pressure; INR, international normalized ratio; PT, prothrombin time; SBP, systolic blood pressure.

^aThe American College of Cardiology suggests that select patients with stroke may benefit from thrombolytic therapy within 4.5 hours of the onset of symptoms.

Conclusion

PE is a relatively common and serious complication of VTE disease. Its incidence appears to be steadily increasing, possibly due to earlier recognition of symptoms and more accurate diagnosis. The increased accuracy of CTA in detecting PE is an important milestone in this regard. The overall mortality risk is directly related to abnormalities of gas exchange in the pulmonary vasculature and cardiovascular complications resulting from obstruction, which lead to increase in pulmonary vascular resistance and RV pressure overload and RV systolic dysfunction. The underlying cardiopulmonary disease status also contributes significantly to above-mentioned hemodynamic complications. Inherited and acquired risk factors like blood dyscrasias, immobilization post-surgery, and malignancy can increase the likelihood of developing VTE and PE. Anticoagulation treatment is mandatory and needs to be initiated as soon as the diagnosis of PE is established. Newer (novel) oral anticoagulation agents are now available in the market and show promise in being used like warfarin, as parenteral agents, in the treatment of PE.
