ABSTRACT
This study sought to compare cardiovascular and perceptual responses to blood flow restriction (BFR) exercise using various pressure and load combinations. Fourteen participants completed four sets of BFR elbow flexion using 10, 15 and 20 % 1RM with 40 and 80 % arterial occlusion pressure (AOP). AOP was measured before and after exercise. Perceived exertion (RPE) and discomfort were assessed before exercise and after each set. Data presented as mean (95 % CI), except for RPE and discomfort: 25th, 50th, 75th percentiles. AOP increased post-exercise (p < 0.001) with larger magnitudes seen when increasing load and pressure (p < 0.001) [e.g., 10/40 ΔAOP: 21 (10, 32) mmHg vs. 20/80 ΔAOP: 62 (45, 78) mmHg], which also augmented RPE (p < 0.001) [e.g., 4th set 10/40: (7, 8.5, 12) vs. 4th set 20/80: (12.75, 15.5, 17.25)] and discomfort (p < 0.001) [e.g., 4th set 10/40: (0.75, 2, 4.25) vs. 4th set 20/80: (4.25, 6, 8.8)]. Volume increased via greater loads (p < 0.001), and participants only reached failure during 20 % 1RM conditions [20/40: 74 (74, 75) repetitions; 20/80: 71 (68, 75) repetitions]. When performing BFR exercise with very low loads the magnitudes of the cardiovascular and perceptual responses are augmented by increasing the load and by applying a higher relative pressure.

Introduction
Blood flow restriction in combination with low load resistance training has been shown to increase muscle size comparably to high load resistance training [15]. As high load resistance exercise may place a large mechanical stress on the joints, blood flow restriction exercise may be an efficacious alternative for a variety of populations (e.g., elderly, injured, athletic) aiming to increase or maintain muscular fitness. However, for a training modality to be effective it must be adhered to by the target population. Thus, it must be safe and should be perceived favorably by those participating in the particular modality of training. Recently, concerns about an exaggerated cardiovascular response following blood flow restriction exercise have been proposed [24] as an argument against the widespread implementation of this training method. In an effort to resolve these concerns, it has been recommended that restriction pressures be made relative to the cuff being used [11, 18] and the limb circumference [11, 17] of each individual. This not only leads to the stimulus being relative to individual differences, but it also ensures practitioners are not inadvertently applying an occlusive stimulus [12].

Thus far, the cardiovascular response to blood flow restriction exercise in the upper body using these relative applied pressures has only been characterized when exercising with 30 % of one repetition maximum (1RM) [4] though loads lower than that could be effective for increasing muscle size [1–3, 13, 14]. Some evidence suggests that higher pressures are needed to elicit muscle growth when using very low loads (20 % 1RM) [16]. It remains to be seen, however, how moderate and higher relative pressures augment the cardiovascular response when exercising at such a low load. Additionally, the perceptual responses to varying levels...
of relative pressure with these very low loads may dictate compli-
ance as participants may be less apt to engage in a particular form
of exercise that they perceive as intolerable. The aim of this study
was to determine the cardiovascular and perceptual responses to
blood flow restriction exercise using very low loads in conjunction
with moderate and high relative restrictive pressures.

Methods

Participants

Fourteen participants (11 males and 3 females) volunteered to par-
ticipate in the study. All had performed resistance training at least
twice a week for the previous six months and were familiar with the
dumbbell elbow flexion (biceps curl) exercise. Participants were el-
gible for inclusion to the study if they: were within the age range
of 18–35 years, did not use tobacco, had a BMI ≤ 30, abstained from
exercise in the 24 h previous to testing, abstained from caffeine in
the 8 h prior to testing, ingested no food within 2 h of testing, avoid-
ed the consumption of alcohol in the previous 24 h, and if they were
free of any orthopedic injury preventing exercise. Additionally, par-
ticipants had to meet less than two of the following risk factors for
thromboembolism to be considered for inclusion: currently taking
warfarin, family or personal history of deep vein thrombosis, or fam-
ily or personal history of pulmonary embolism [22]. All participants
were informed of the experimental procedures as well as any po-
tential risks that were associated with the study before giving writ-
ten informed consent. The University’s Institutional Review Board
approved this study, and it meets the ethical standards set forth by
the International Journal of Sports Medicine [10].

Experimental design

Participants made four visits to the laboratory, each one at the
same time of day, separated by at least five but no more than ten
days. Visit 1 consisted of paperwork followed by measurements of
height, body mass, standing arterial occlusion pressure, and elbow
flexion (biceps curl) one repetition maximum (1RM). Participants
were then familiarized with blood flow restriction exercise. For each
visit thereafter, two of the six possible conditions were tested (one
with each arm) until all six conditions were applied over the three
different visits. Each condition was a different combination of load
(10, 15, and 20 % of 1RM) and relative restriction pressure (40 and
80 % AOP). For each testing condition, the participant began by
resting quietly (10 min before condition 1, and 15 min before con-
dition 2) followed by a measurement of standing arterial occlusion
pressure on each arm using a hand held Doppler probe. Afterwards,
participants performed four sets (goal repetitions: 30, 15, 15, 15)
of unilateral elbow flexion exercise in combination with blood flow
restriction. During the 30 s of rest observed between each set of
exercise, participants were asked for their ratings of perceived ex-
erion (RPE) and level of discomfort. Immediately following the last
set of exercises, standing arterial occlusion pressure was measured
again in the exercised arm. Participants then rested quietly for
15 min after which all testing was repeated in the opposite arm
only, using a new combination of load and pressure. Arterial occlu-
sion pressure was reassessed (in the arm to be exercised) before
beginning condition 2. This was to ensure that the cardiovascular
response was not still elevated due to having undergone condition
1. After both conditions were tested (one per arm), the visit was
over and the next four conditions were completed during the sub-
sequent visits (two conditions per visit). The order of the arms,
loads, and restriction pressures used for visits 2–4 were randomized
during visit 1 using a random sequence generator. All restrictive
pressures applied were based upon the arterial occlusion pressure
measurement taken immediately prior to each exercising condi-
tion.

Arterial occlusion pressure

Standing arterial occlusion pressure was measured before each
bout of exercise, and immediately after exercise. A 5 cm wide, nylon
cuff (SC5 Hokanson, Bellevue, WA) was placed on the most proxi-
mal portion of the participant’s upper arm. A hand-held Doppler
probe (MD6, Hokanson, Bellevue, WA) was placed at the wrist over
the radial artery until an auditory signal of blood flow was found.
The cuff was slowly inflated using an E20 Rapid Cuff Inflator (Ho-
kanson, Bellevue, WA) until there was no longer an indication of
blood flow from the Doppler probe. The lowest cuff inflation pres-
sure at which the blood flow distal to the cuff was no longer detect-
able was defined as arterial occlusion pressure. The post-exercise
arterial occlusion measurement was taken immediately after exer-
cise by increasing the inflation pressure off the cuff, which was al-
ready inflated during the bout of exercise. Once arterial occlusion
was determined the cuff was immediately deflated and removed
from the upper arm.

One-repetition maximum

One-repetition maximum for unilateral elbow flexion was assessed
in both arms on visit 1, in order to determine the appropriate rela-
tive load for all conditions. Participants began the test following a
warm up of 5–10 repetitions using 30 % of an assumed maximum.
Each attempt during testing began with participants standing with
their feet shoulder width apart, their heels and back against a wall,
and the arm fully extended and supinated by their side. Once in
proper position they were handed a loaded dumbbell and encour-
gaged to complete a full range of elbow flexion while maintaining
an upright position. Attempts began by completing one repetition
at an estimated 60–75 % of maximum, and the load was progres-
sively increased until the participant was unable to lift a load great-
er than their previous successful attempt. After each attempt par-
ticipants were given a rest period before attempting the next load.
An attempt was deemed unsuccessful, if the participant could not
complete the full range of motion, or if they were unable to main-
tain strict form with their heels and back against a wall. One-repe-
tition maximum was determined as the greatest load a participant
was able to lift properly through a full range of motion.

Blood flow restriction protocol

Blood flow restriction was applied by placing a 5 cm wide nylon
cuff (SC5, Hokanson, Bellevue, WA) to the proximal portion of the
exercising limb and inflating it to either 40 or 80 % of pre-exercise
arterial occlusion. These particular pressures were investigated as
they are often used in the blood flow restriction research
centric portion of the lift.

nome cadence of 1 s for the concentric portion and 1 s for the eccentric portion of the lift.

between each set [9]. Each repetition was performed to a metronome cadence of 1 s for the concentric portion and 1 s for the eccentric portion of the lift.

[4, 7, 14, 27] and both have been shown to elicit muscle adaptation [8, 15]. After inflation the participants performed four sets of elbow flexion with one of three experimental loads (10, 15, or 30 % of 1RM). The goal repetitions were modeled from a commonly used blood flow restriction protocol of 30, 15, 15, 15 with 30 s of rest between each set [9]. Each repetition was performed to a metronome cadence of 1 s for the concentric portion and 1 s for the eccentric portion of the lift.

**Ratings of Perceived Exertion (RPE) and discomfort**

Participants were informed in depth on how to rate their exertion (RPE) and discomfort to ensure they understood the scale being used. In short, participants were told that a rating of 6 meant they were not exerting themselves at all, and a rating of 20 meant that they were giving maximal effort and would be unable to exert themselves any further. Individuals were asked to rate their level of exertion using the standard Borg 6–20 scale [5, 20]. This was asked immediately prior to beginning exercise, and then again immediately following each set of exercise. A rating of discomfort was obtained using Borg’s Discomfort Scale (CR10 + ) [5, 20]. It was explained to participants that the scale was rated from 0–10 with a score of 10 representing their previously worst felt discomfort. They were then instructed that a rating of 10 was their reference point, and they could exceed 10, if the discomfort they felt was greater than what they have ever felt before. Participants were then asked whether they had any questions. To ensure that all participants fully understood the scale prior to exercise, they were provided the opportunity to request any clarification and they were asked if they understood how to rate their level of discomfort. Ratings of discomfort were taken immediately before exercise, as well as 20 s after sets 1, 2, and 3, and immediately after set 4. Discomfort was taken 20 s after each set because participants in previous studies anecdotally noted greater discomfort later in the rest periods and it was thought that this provided a more accurate representation of the level of discomfort caused by the exercise protocol [8].

**Statistical analyses**

All data were analyzed using SPSS 23.0 statistical software package (IBM, Chicago, IL, USA). To detect any interaction effect of condition and time for arterial occlusion, a 6 (condition) x 2 (time) repeated measures analysis of variance (ANOVA) was used. If there was a significant interaction effect, a one-way repeated measures ANOVA was used to reveal differences across conditions within each time point, and a paired samples t-test was used to find differences between time points within each condition. For comparisons of perceptual responses (RPE and discomfort), a Friedman non-parametric test was used to reveal any differences between conditions within each time point (pre, set1, set 2, set 3, set 4). If a significant difference was revealed, Wilcoxon related samples non-parametric tests were used to find where those differences occurred. To compare exercise volumes across conditions, a one-way repeated measures ANOVA was used. All data are presented as means and 95 % confidence intervals. For perceptual responses data are represented as 25th, 50th, and 75th percentiles. Statistical significance was set a priori at an alpha level of 0.05.

**Results**

**Participant characteristics**

In total, 3 females and 11 males [mean (95 % CI); Age: 24 (22, 26) years; height: 175.2 (169.0, 181.3) cm; body mass: 83.6 (75.3, 92.0) kg; 1-RM left arm 25.4 (20.6, 30.2) kg; 1-RM right arm 26.1 (21.0, 32.2) kg] completed all testing conditions.

**Arterial occlusion pressure**

For arterial occlusion pressure, there was a significant interaction effect of condition x time (p < 0.001). Follow-up tests revealed that arterial occlusion pressure was increased from pre to post (p < 0.001) across all conditions. There were no significant differences across condition at pre (p = 0.659). At post, however, there were significant differences (∗ Fig. 1a, p < 0.001) with the arterial occlusion being augmented by the greater applied pressure (80 % > 40 %) and in some cases a heavier exercise load (20 % > 15 % > 10 % > 1RM). The mean change (95 % CI) in arterial occlusion pressure from pre to post for each condition can be found in ∗ Fig. 1b. Although applied pressure remained the same, it was based upon the percentage of pre-arterial occlusion, and since ar-

terial occlusion increased post exercise the percentage of pressure being applied was lower (▶ Fig. 2). It should be noted that for the post measurement of arterial occlusion pressure, one participant did not reach full occlusion following exercise in the 10/80 condition. This is due to the limitation of the E20 Rapid Cuff Inflator, which does not exceed 300 mmHg. Thus, for that measure we recorded arterial occlusion as 300 mmHg, and it was used in the analysis.

Ratings of Perceived Exertion (RPE)

There were no significant differences in RPE across conditions at pre (▶ Table 1, p = 0.306). Significant differences were revealed across condition within each set of exercise (▶ Table 1, p < 0.001) with the RPE generally being higher with greater loads and pressures.

**Ratings of discomfort**

Similar to RPE there were no differences in discomfort across conditions at pre (▶ Table 1, p = 0.203). There were significant differences across conditions within each set of exercise (▶ Table 1, p < 0.001) with discomfort generally being higher with greater loads and pressures.

**Exercise volume**

For exercise volume there was a significant difference across conditions (p < 0.001). In general, volume was greater with increased load, but it was not attenuated with higher pressures (▶ Fig. 3). Since the changes in total volume are driven by the experimental differences in load, we also chose to compare the total repetitions completed between conditions to determine whether participants were reaching failure in any of the conditions. For total repetitions, there was no significant difference (p > 0.052) across conditions (▶ Table 1), though there were some individuals who were unable to complete the full protocol at 20 % 1RM. For example, one person was unable to complete all repetitions using 20 % 1RM and 40 % BFR and four participants were unable to complete all repetitions using 20 % 1RM and 80 % BFR.

**Discussion**

In the current study, arterial occlusion pressure significantly increased immediately following blood flow restricted exercise, resulting in the applied pressure dropping to a lower percentage of arterial occlusion. Larger increases in post exercise arterial occlusion pressure were observed with increases in load and applied pressure. Similarly, ratings of perceived exertion and discomfort were greater with increased loads and higher pressure. Taken to-
gether the data suggests that both the cardiovascular and perceptual responses to blood flow restriction exercise with very low loads are augmented by increasing the load lifted and increasing the relative restriction pressure applied.

**Cardiovascular response**

In order to determine the cardiovascular response to blood flow restricted exercise using very low loads, we measured the post arterial occlusion pressure immediately following the cessation of the last set of exercises. Although this is not necessarily a traditional measure of systolic blood pressure since it is measured with a non-standard narrow cuff (5 cm) [17], it is similar, and allows us to capture the cardiovascular response to this type of exercise (i.e. unilateral bicep curl) without deflating and removing the cuff potentially missing the true cardiovascular response. The pressure required to completely occlude arterial blood flow increased following exercise in all conditions and was augmented by increasing the load and by applying a higher pressure. The mean change in arterial occlusion pressure ranged from 21 mmHg in the 10/40 condition to 62 mmHg in the 20/80 condition. The increase at lower loads and pressures is similar to the average increase of 24 or 26 mmHg (depending on the cuff width) observed immediately following (prior to deflation) bilateral leg extension exercise with 20 % 1RM [23]. It should be noted that the pressure for the Rossow et al. study was based on brachial systolic blood pressure, which makes it difficult to determine the relative pressure applied to the lower body [17, 18].

In the upper body, Brandner et al. [6] found that systolic blood pressure changes following traditional high load unilateral bicep curl exercise (80 % 1RM) were similar (approx. 50 mmHg change) to a continuous blood flow restriction protocol using 20 % 1RM. When comparing this cardiovascular response to blood flow restricted exercise using a relative pressure of 40 % arterial occlusion, Barnett et al. [4] observed a mean increase in arterial occlusion pressure of approx. 31 mmHg immediately following unilateral bicep curl exercise. That increase resulted in the applied pressure of 40 % arterial occlusion before exercise to decrease to approx. 32 % of arterial occlusion post exercise, which was similar to the moderate pressure conditions in the current study, whereas the high pressure conditions (80 % of AOP) decreased to around 56–60 % of arterial occlusion. This may be important given the possible existence of a minimum pressure threshold in which pressure is required to be beneficial for adaptation [21]. If this threshold does in fact exist, it may be necessary to use a higher restriction pressure to keep the applied pressure above that threshold. Although higher pressures may not be necessary with loads such as 30 % of 1RM or greater [8], they might be necessary with loads less than 30 % 1RM. For example, a long term training study found that muscle size increases were lower when using 20 % of 1RM in combination with a moderate blood flow restriction pressure (40 % arterial occlusion) compared to a group using the same load combined with a high pressure (80 % arterial occlusion) [16]. Even though applying a higher pressure combined with very low loads does augment the cardiovascular response (mean increase of 21–62 mmHg), it should be noted that the magnitude of change is similar to that observed with traditional high load resistance training (approx. 50 mmHg) [6]. Thus, resistance exercise using very low loads in combination with moderate or high relative BFR pressures does not seem likely to pose an increased cardiovascular health risk when compared to traditional resistance exercise.

**Perceptual response**

To make inferences about possible adherence to a blood flow restriction training protocol, participants were asked to rate their level of perceived exertion and discomfort following each exercise condition, using a combination of very low loads with moderate or high restriction pressures. Ratings of perceived exertion were greater with increases in load and pressure, with the exception of 20 % 1RM conditions where RPE was similar between moderate and high pressure conditions for set 4. Although RPE is expected to be greater when increasing the load, it was augmented by pressure as well. Blood flow restriction may exacerbate RPE over traditional, load-matched exercise by stimulating cutaneous afferent nerves. In turn, this may lead to an increased central descending drive causing an exaggerated perception of work [26]. When compared to a control group using the same load (20 % 1RM), Yasuda et al. [29] observed an increased RPE when applying blood flow restriction, but there were no differences when increasing the pressure from 98 mmHg.
Ratings of discomfort were increased in each relative loading condition when applying a high pressure versus a moderate pressure. Higher pressures may result in a greater accumulation of metabolic byproducts within the limb [28], increasing the perception of discomfort through a stimulation of group III and IV afferent fibers [25]. However, previous studies have not always found a relationship between whole blood lactate and ratings of discomfort [19], suggesting that there may be other underlying physiological and/or psychological mechanisms associated with discomfort during blood flow restricted exercise. When comparing a range of moderate to high relative pressures during blood flow restriction exercise with 30 % 1RM, Loenneke et al. [20] found no real differences in discomfort. This is in contrast to our observations and those of Counts et al. [8], where discomfort was greater in a high pressure condition versus a moderate pressure condition. Discrepancies in studies may be due to baseline strength of the participants or the timing of when participants were asked their level of discomfort. Relative to the Counts investigation [8], participants in the Loenneke study [20] were lifting a higher absolute load, and it is possible that at 30 % 1RM this may, in itself, contribute to greater discomfort and mask any effect that pressure may have. In participants with high baseline strength, such as those in the present investigation, augmented discomfort by increasing pressure may only be observed when using loads less than 30 % 1RM. Another possibility is that Loenneke et al. [20] asked participants to rate their discomfort immediately following each set of exercise, whereas the current participants were asked twenty seconds after the cessation of each set. This time point may better capture the true discomfort of restricting blood flow as the skeletal muscle pump is inactive and very little blood, if any at all, is leaving the exercised limb. Altogether RPE and discomfort are greater when increasing load and pressure.

Repetitions and volume

Previous studies have shown that total exercise volume using 30 % 1RM was attenuated by increasing the percentage of relative blood flow restriction pressure applied [8, 20]. In the current study, exercise volume was not attenuated by pressure for the majority of participants. Given the fact that participants were lifting such low loads and were able to complete nearly all repetitions for each condition the differences in volume are explained by the increase in load. For that reason, we also chose to investigate the total number of repetitions completed and found that not everyone was able to complete all of the repetitions at the 20 % load. Thus, if implementing a common goal repetition scheme of 30-15-15-15 with blood flow restriction exercise at 20 % 1RM, applying a higher pressure may induce fatigue more quickly than moderate pressures, which may be beneficial for certain populations looking to increase or maintain muscle fitness with minimal joint stress.

Limitations

The current study is not without limitations. First, there was no quantification of blood flow, only the detection of blood flow cessation with a handheld Doppler probe, which means 40 % or 80 % of arterial occlusion pressure is not necessarily a 40 % or 80 % reduction in blood flow. Second, the cuff used to determine the cardiovascular response was a narrow 5 cm cuff, and responses could be different with varying cuff widths, including that of a clinical blood pressure cuff. However, we believe that the best way to capture the cardiovascular response immediately after exercise was to use the cuff already applied and inflated for blood flow restriction and examine the arterial occlusion pressure changes. Finally, the testing of two conditions in the same day can be viewed as a possible limitation. The reperfusion of blood flow and circulating endothelial factors as a result from the first exercise bout could have influenced the second condition, which was tested in the contralateral arm. However, rest was taken between the conditions to allow for a washout period. Since AOP was assessed before all exercise conditions, and immediately before the second exercise protocol, we ran a retrospective dependent t-test to determine that there were no statistically significant differences between AOP of arm 2 assessed before any exercise and after the rest period following condition 1. The mean differences (95 % CI) between AOP measurements were 2.7 (−1.8, 7.4) mmHg for visit 1 (p = 0.219), 1.7 (−8.8, 5.4) mmHg for visit 2 (p = 0.614), and 1.1 (−6.7, 4.4) mmHg for visit 3 (p = 0.666). Therefore, if in fact there was a residual effect of condition 1 on condition 2, it was minimal in comparison to what was observed from the exercise protocol itself.

Conclusions

The results of the current study have shown that when resistance exercise is performed using very low loads in combination with blood flow restriction the cardiovascular and perceptual responses are augmented by an increase in the relative load being used for exercise, as well as an increase in the relative pressure being applied for blood flow restriction. When compared with previous studies implementing traditional high load training, the magnitude of the cardiovascular response to blood flow restriction is similar and does not appear to pose an additional safety concern. Although RPE is augmented by load and pressure, it is less than that previously observed with high load training, suggesting that RPE may not be a limiting factor of participant adherence; it could, however, be limited by discomfort which was also augmented with higher pressures. Blood flow restriction training studies using very low loads with moderate and high pressures should be performed to determine the long term effects on muscle adaptation, as well as cardiovascular and perceptual responses.
