Gastric cancer is an important screening target, particularly in countries with high gastric cancer incidence and mortality, such as East Asian countries. Endoscopy plays an increasingly important role in screening and diagnosis of gastric cancer. For instance, in Japan, endoscopy has been recently accepted as a primary tool in population-based gastric cancer screening [1]. Endoscopy is also a vehicle for modern gastric cancer treatments, such as endoscopic submucosal dissection (ESD) [2–4]. Although advanced gastric cancer still has a poor prognosis, patients with early-stage disease treated with ESD are likely to have favorable outcomes [3–5]. For that reason, early detection of gastric cancer is important and endoscopy is a critical tool for its early detection, diagnosis, and treatment.

Endoscopy is considered to be the most powerful tool for detecting gastric cancer [6]; however, it does not always find existing cancers, and its miss rate has been examined in several studies. In 2014, a meta-analysis by Menon et al., published in *Endoscopy International Open*, examined how commonly upper gastrointestinal (GI) cancer is missed at endoscopy [7]. The authors defined missed cancers as cancers that had not been diagnosed by endoscopies performed within 3 years before diagnosis, based on the hypothesis that mucosal cancer has a 2–3-year doubling time [8]. The study concluded that 11.3% of upper GI cancers were missed at endoscopy performed within 3 years before the diagnosis, and showed that 0.25% of all the endoscopic procedures missed existing upper GI cancers. Although these data are important and informative, interpreting the results can be difficult because the examined upper GI can-

cers included both gastric cancers and esophageal cancers, and also cancers at various stages. Considering the heterogeneity of these lesions, the limitations of this study (particularly the definition of missed cancer based on a specific interval between diagnosis and preceding endoscopy) cannot be ignored; further data on missed cancers from studies performed in different study methods are therefore needed.

In this regard, the paper by Shimodate et al. from a Japanese institution published in *Endoscopy International Open* 2017, provides us with a wider perspective [9]. The authors examined the miss rate of gastric superficial neoplasia (GSN) by reviewing GSN patients' earlier endoscopic records, rather than defining missed cancers by the interval between diagnosis and preceding endoscopy. Although the study has several limitations (e.g. retrospective design, possible selection bias, and lack of full information on preceding endoscopies), five endoscopists in this study actually reviewed the images of the preceding endoscopies and judged the existence of the missed lesions. The study concluded that the miss rate for GSN was 75.2%. The rate seems surprisingly high, but it is necessary to understand the meaning of the value appropriately. This value means not the miss rate of GSN among all endoscopic procedures but the proportion of GSNs overlooked at the preceding endoscopies among all GSNs. In addition, because missed cancers were defined quite differently in this study than in the Menon meta-analysis, their miss rates are difficult to compare [7]. However, even after considering the new definition for miss rate in the Shimodate study and the study's possible selection bias, the

rate still seems high, probably because the target of the study, GSN, is more difficult to detect than most other upper GI cancers (as the authors mention).

This high rate indicates room for improvement in early detection of gastric cancer. The key factors for such improvement include better training of endoscopists and further advancement of endoscopy. Establishment of an improved training system for endoscopists and quality assurance for endoscopy are essential for more successful gastric cancer screening using endoscopy [1,10,11]. With regard to the advancement of endoscopy in detection and diagnosis of upper GI cancers, image-enhanced endoscopy with/without magnification has been expected to contribute to the improvement [12,13], although further investigation is necessary, particularly for its usefulness in detecting GSN.

The finding of the study that GSN is easily overlooked, even by endoscopists certified by the Japanese Gastrointestinal Endoscopy Society, also makes us realize the necessity of establishing the appropriate surveillance program after endoscopy. In considering the surveillance program, the data on the natural course of missed GSN examined in the study also provide us with important information. The authors examined the clinical course of missed GSNs and showed that only 8.5% of them progressed to advanced cancer during the mean interval of 39.3 months. Based on the low cumulative incidence rate of progression to advanced cancer (0.8%) of missed GSNs at 3 years after endoscopy and increased incidence after 3 years, the authors commented that surveillance endoscopy should be performed at least every 3 years after endoscopy to detect early-stage gastric cancers. The obtained data are important and the comment on surveillance seems logical, but more detailed consideration is necessary regarding the issue of surveillance. From the perspective of limited endoscopy resources, risk stratification of individuals is required, instead of performing surveillance endoscopy within 3 years after the preceding endoscopy for all individuals. Therefore, how to incorporate risk factors for gastric cancer, such as the status of *Helicobacter pylori* infection [14] and atrophic gastritis [15], into both screening and surveillance programs should be investigated. A large prospective study in consideration of these factors is warranted.

Another aspect of the miss rate of upper GI cancer is that the rate might be used as a quality indicator of upper GI endoscopy [1,10,11]. Quality indicators have been well studied in colonoscopy, whereas such indicators for upper GI endoscopy have room for further investigation. In the future investigation of quality indicators for upper GI endoscopy, it will be possible that the miss rates of upper GI cancers and GSN are examined as candidates for the indicators after discussion on the definition of the miss rates.

In this editorial, we discussed the miss rate for GSNs. Based on the reported high miss rate, improved training for endoscopists, further research and development of endoscopy in detection and diagnosis, and establishment of appropriate surveillance programs are essential. It is also critical that each endoscopist should always consider the risk of overlooking important lesions, such as GSNs, and try to achieve best performance in every upper GI endoscopic procedure.
