A frank perforation of the upper gastrointestinal tract is usually repaired surgically. With the advent of endoscopic clipping devices, patients with gastric [1], duodenal [2], and colonic [3,4] perforations have been treated endoscopically. We report the successful use of an endoscopic clipping device to treat a duodenal perforation that occurred during an endoscopic ultrasound examination.

A 78-year-old white woman with weight loss, abdominal pain, and an enlarged pancreatic head on computerized axial tomography scan, underwent an endoscopic ultrasound examination (Pentax 3630U). No mass was noted during the initial endoscopic ultrasound survey; however, on reintubation of the descending duodenum, a frank perforation occurred. Evaluation of the bulb with a panendoscope (Pentax EG-3440) revealed a 6-mm slit-like perforation site (Figure 1a). Three endoclips were successfully applied to reapproximate the mucosal surface of the perforation. Two additional clips were then placed beneath the initial clips (Figure 1b). A nasogastric tube was inserted and treatment with broad-spectrum antibiotics was begun. No signs of peritonitis developed. A gastrografin swallow performed 1 day later showed no evidence of perforation other than intra-abdominal free air. At 1 month after discharge the patient underwent uneventful laparoscopic cholecystectomy.

Despite the endoscope’s 12-mm diameter, 4 cm rigid tip, and oblique viewing angle, perforation of a viscus during an endoscopic ultrasound examination is an infrequent occurrence [5]. Following a perforation, there is usually minimal peritoneal soiling if the perforation is closed promptly. Because of some concern about early clip migration, which would result in a reopening of the defect, the mucosa was first approximated with three clips, then two additional clips were placed beneath these, presumably deeply into the submucosa. For a select group of patients with a high surgical risk, the clinician’s familiarity with the use of endoclips, and their immediate availability and proper deployment, can avoid a laparotomy when a small, well-visualized perforation occurs during endoscopy.
