Bacterial infections are common in cirrhotic patients as a result of defects in their immune defense system [1]. We report two patients with cirrhosis who developed meningitis following upper endoscopy.

A 41-year-old man with a history of hepatitis C-related post-hepatitic cirrhosis was admitted to our intensive care unit because of hematemesis. The patient underwent an emergency upper endoscopy, which showed esophageal varices. He was treated by ligation of the varices, and intravenous antibiotic prophylaxis with ceftriaxone was started. Twelve hours later, the patient suddenly became drowsy, his body temperature rose to 40.8°C, and he then had a generalized seizure. Cerebral computed tomography (CT) was normal. A lumbar puncture revealed purulent cerebrospinal fluid (CSF). CSF antigen tests and cultures were negative. Ceftriaxone and amoxicillin were administered intravenously for 2 weeks. The patient was discharged from hospital without any neurological sequelae.

A 58-year-old man was admitted with Child B alcoholic cirrhosis. Four days after an upper endoscopy was performed he became confused and his temperature rose to 40°C, and he then had a generalized seizure. Cerebral computed tomography (CT) was normal. A lumbar puncture revealed purulent cerebrospinal fluid (CSF). CSF antigen tests and cultures were negative. Ceftriaxone and amoxicillin were administered intravenously for 2 weeks. The patient was discharged from hospital without any neurological sequelae.

Although bacterial meningitis seems to be rare in cirrhosis [2], previous reports have suggested a causal relationship between meningitis and upper gastrointestinal endoscopy [3]. The diagnosis of meningitis in cirrhosis can be difficult for several reasons: the clinical presentation of meningitis in cirrhosis has special characteristics, such as the absence of nuchal rigidity; the condition frequently presents as a febrile coma [1]; and drowsiness or confusion can be masked by the encephalopathy. In addition, cultures can be negative after antibiotic prophylaxis [4], as in our first case.

Upper endoscopy requires manipulation of the oropharyngeal areas, which can damage the oral mucosa, and be followed by transient bacteremia (with commensal organisms) in 2.5% of cases, as in the second case. Alcoholic patients often have poor oral hygiene, and any septic foci should be treated before upper endoscopy is performed [5].
