Orbital Hemorrhage as a Complication of Gastroscopy

Diagnostic gastroscopy is a safe procedure with a complication rate of below 0.1%. These complications are mostly cardiopulmonary and, sometimes, rare instances of perforation, bleeding and infection (1,2). We report the first case of an orbital hemorrhage secondary to gastroscopy.

A 35-year-old woman, who stated that she did not take regular medication although she had suffered from left-sided migraine for many years, had a prior neurological examination, including an enhanced computed tomography (CT) scan, with normal findings.

At a previous gastroscopy an insufficient cardia had been diagnosed. Because of suspected hematemesis, another gastroscopy with local pharyngeal anesthesia was performed 3 years later by a senior endoscopist using an Olympus videogastroscope. Apart from moderate attacks of retching, nothing abnormal was registered, but immediately after the examination the patient complained of pain behind the left eye. Despite absence of any clinical signs of damage to the eye, the patient was sent for ophthalmological examination. During the next hour diplopia developed and there was ecchymosis of the eyelids on the left side. The left globe was protruded 6 mm and infraducted with restricted motility (Figure 1). Visual acuity, intraocular pressure, pupillary reactions and ophthalmoscopic appearance were normal bilaterally. A CT scan demonstrated a hematoma causing displacement of the eye (Figure 2), with restitution 3 and 7 weeks later. Gadolinium-enhanced magnetic resonance imaging (MRI) angiography 5 months later revealed no vascular anomaly and the patient is still well 4 years later.

Spontaneous orbital hemorrhage is uncommon and has been described in connection with venous anomalies and with advanced atherosclerosis, hypertension, anemia and hemophilia being considered as predisposing conditions (3). Straining is another associated factor (3–5), probably causative in our case. As orbital veins have no valves, an unobstructed venous pressure, secondary to an increased intrathoracic pressure, is freely propagated to the orbital veins (3,5). In our patient the intubation-related, transient increase in thoracic pressure, probably exaggerated by the attacks of retching, may have caused the orbital hemorrhage.
