Endoscopic Appearance of a Duodenal Infection by Mycobacterium avium-intracellulare in AIDS

We report here the case of a 37-year-old woman, previously a parenteral drug abuser, with HIV infection diagnosed four years before, who presented with fever, weight loss, severe dysphagia and abdominal pain. Endoscopy showed thickening of the mucosal folds and multiple yellow-whitish nodules in the duodenum, also involving the bulb (Figure 1). A diagnosis of infection by *Mycobacterium avium-intracellulare* (MAI) was established (positive Hemocults and cultures of samples obtained from the antral and duodenal mucosa). The pathological study of the biopsy samples obtained from the duodenum led to the diagnosis of infection by MAI, with a light-microscopic appearance similar to that in Whipple’s disease. A scanning electron-microscopic study was performed, and the most significant finding was visualization of the electrolucent capsule of the rods (Figure 2).

The endoscopic lesions caused by MAI infections have been described as “minute superficial ulcerations throughout the duodenum” (2) or “multiple, somewhat raised, yellow lesions affecting the duodenum” (3). Our patient showed lesions (several yellow-white nodules) that were similar to those described in Whipple’s disease (4) and to those described by Vázquez-Iglesias et al. (3) in MAI infection, except that the lesions were already evident from the beginning of the duodenal bulb, and there were no confluent lesions in the second portion of the duodenum. In addition, in our case, a few antral erosions were seen, which could be similar to the ones described in Whipple’s disease (4); although MAI was detected in the culture, the presence of histological lesions caused by MAI could not be confirmed in the pathological study of the samples.

Various reports have concluded that AIDS enteropathy may mimic Whipple’s disease (4). Our patient also presented with an MAI infection that had the optical appearance of Whipple’s disease. Both conditions produce erythematous macular lesions in the small intestine, with villous widening and foamy macrophages which, using the periodic acid–Schiff reaction method, show the presence of bacillary structures called Sieracki’s structures in Whipple’s disease (2). The differential diagnosis is made using Ziehl’s technique, which is negative in Whipple’s disease and positive in MAI infection. In the latter case, the rods are generally intact and have an electrolucent capsule, while in Whipple’s disease they appear at different stages of intracellular digestion, having a dense capsule, are Gram-positive, suffer binary fission, and disappear under antibiotic treatment (5).
