Trans-ciliary minimally invasive keyhole craniotomy for skull base and vascular lesions

Sir,

Conventional approaches to the anterior and lateral skull base would necessarily include a large craniotomy and possibly an orbitozygomatic osteotomy.\(^1,2\) Approach-related complications include visible scars, increased blood loss during surgery, facial and orbital ecchymosis, and long-term problems such as temporalis muscle atrophy and painful jaw opening.\(^2\) Many skull base lesions can be easily accessed via a minimally invasive keyhole craniotomy using an eyebrow incision. This approach is effective in minimizing surgical trauma, hospital stay, and long-term morbidity.\(^3,4\)

We reviewed the records of all patients operated via the supra-brow approach over the past 5 years in our center. A total of 29 patients had been operated via this approach. Their ages ranged between 1 and 64 years; there were 19 adults and 10 children; 17 patients were males. Fifteen patients were operated for aneurysms and 14 patients for other lesions [Table 1].

All except one giant cavernous segment aneurysm presented with subarachnoid hemorrhage. All patients were operated in the early postrupture period (<5 days); the subarachnoid space was thus filled with dense clots in all instances [Figure 1]. We did not, however, have to use lumbar cerebrospinal fluid drainage in any of the cases. Intraoperative rupture occurred in 2 cases; the bleeding could be controlled by rapid temporary clipping of the parent vessel in both instances. In the tumor group, gross total excision could be achieved in 12 of the 14 patients [Figure 2]. In 2 patients with craniopharyngioma, tumor residue was left due to dense

The duration of the surgical procedures varied between 1.5 and 3.5 h (1 h < the conventional procedures at our center). The average blood loss was <250 ml and none of the patients received a blood transfusion.

All patients tolerated the procedure well and required analgesics for a maximum of 5 days. None of them had any difficulties in chewing or swallowing. Six patients had periorbital ecchymosis which resolved in 5–7 days [Table 2]. The scar of the operative incision was inconspicuous at 6 weeks follow-up. Four patients in this group had a receding hairline with partial baldness, and the cosmetic outcome was especially good in them [Figure 3]. The wound healed well in children as well, and there was no loss of hair on the eyebrow [Figure 4].

The application of keyhole approaches depends on an exact knowledge of neuroanatomy. The introduction of long bayonetted instruments has made minimal access surgery safe.\(^3,4\) There is a definite learning curve to implement these approaches.\(^5\) The addition of an endoscope can provide a “third eye,” permitting the surgeon to peer into blind crevices not visualized through the microscope.

The mini-frontal keyhole craniotomy via a supra-brow incision should become a standard part of a neurosurgeon’s armamentarium to tackle skull base lesions.
