Introduction

Synchronous malignancies are rare occurrences in children and pose a challenge in terms of chemotherapy and surgery.\(^1\) This challenge is intensified if there is an association with TP53 which predisposes the individual to development of tumors when exposed to chemotherapy or radiotherapy.\(^2\) This is such a case which had high-risk malignancies otherwise treated by high-dose chemotherapy and/or radiotherapy, but because associated with TP53 and MLH3 gene mutations, management strategy had to be changed. The rarity of the gene mutations associated makes it a unique case.

Li-Fraumeni syndrome (LFS) is a familial cancer syndrome associated with multiple malignancies and TP53 gene mutation.\(^3\) This case report comes close to being labeled as LFS.

Case Report

An 11-month-old male child was admitted with the complaints of hoarseness of voice and hirsutism from 8 to 9 months of age. The child had generalized coarse hair overgrowth over the entire body along with weight gain for which an endocrine consultation was done. Hormonal assay and radiological imaging studies were done after the endocrine consult.

Medical investigations revealed high levels of serum cortisol (20.85 µg/dL) and elevated testosterone levels (free testosterone 250 ng/dL and dihydrotestosterone 2500 ng/dL). Urinary vanillylmandelic acid levels were normal, and alpha-fetoprotein level raised to 912 ng/mL (normal <10 ng/mL).

Radiological investigation revealed a mass in the left adrenal gland, which was heterogeneous and well encapsulated with areas of focal calcification seen within the tumor [Figure 1a]. There was an exophytic mass in the segment VI of the liver seen without any extrahepatic, inferior vena cava (IVC), portal vein, or nodal involvement [Figure 1b]. Computed tomography also revealed a well-encapsulated mass in the posterior mediastinum extending between the T4 and T7 vertebrae without any intraspinal extensions [Figure 1c]. The lungs were clear of metastasis, so was the brain.

There were no dysmorphic features present in the child and no history of malignancy in the siblings.

Abstract

We report the case of an 11-month-old child who presented with a change in voice, increased weight, and hirsutism, who was also found to have elevated levels of serum cortisol and testosterone, showing three synchronous malignancies in the liver, left adrenal gland, and posterior mediastinum. Clinical exome sequencing report revealed germline TP53 (P177A) and MLH3 (V741P) mutations with NMYC positive neuroblastoma. At the outset, this may look like a Li-Fraumeni syndrome (LFS) with TP53 germline mutation but lacks other features to be termed as LFS or Li-Fraumeni-like syndrome. The gene mutation variant found in this case (P177A) is a novel missense mutation which has never been reported, and the MLH3 gene mutation variant F741P has not been previously associated with any of the malignancies seen in this child.

Keywords: Adrenocortical malignancy, hepatoblastoma, mismatch repair gene, neuroblastoma, synchronous malignancy

The mother had a history of six previous abortions and hormonal treatment during pregnancy. The abortions were not spontaneous but for wanting a male child. The child’s father was formerly treated for renal cell carcinoma, underwent partial nephrectomy 5 years ago, has not received any chemotherapy postprocedure, and is symptom free. There was no other family history of any malignancy.

There were three masses in this child and in order to get a bearing as to which is primary and which is metastasis, we decided to biopsy one of them and the safest was to perform a liver biopsy. He underwent an ultrasound-guided liver biopsy under corticosteroid cover, and it was reported as fetal variant hepatoblastoma (ICD-O-3 code 8970). Further, a right thoracoscopic biopsy was done to rule out metastasis, but it was reported to be a neuroblastoma stroma poor type (ICD-O-3 code 9490).

After ruling out adrenal medullary involvement (by urinary vanillylmandelic acid and homovanillic acid level) to prevent the intraoperative adrenal storm, he underwent a left adrenalectomy (Figure 2a) and excision of hepatoblastoma under corticosteroid cover (Figure 2b). The left adrenal mass was reported as adrenocortical malignancy (ICD-O-3 code 8370) without a breach in the capsule and the hepatoblastoma was of fetal variant without any hepatic vein, IVC, or extrahepatic involvement and clear margins of resection. The chest mass was excised 2 weeks later, and its biopsy was reported as neuroblastoma, which was well differentiated and of stroma poor type [Figure 2c].

Hormonal evaluation post tumor excision revealed a reduction in the levels of cortisol (2.0 µg/dL), testosterone (free testosterone 0.1 ng/dL and dihydrotestosterone 27 ng/dL), and alpha-fetoprotein (3.0 ng/mL). Currently, the levels of the elevated hormones have normalized, and he is off steroids which were stopped after tapering doses.

Because the child has three histologically distinct malignancies, gene mutation studies were done which revealed germline TP53 gene mutation (c. C530G, p. Pro177Arg) with allelic ID 468390 and MLH3 gene (c. G2221T, p. Val741Phe) mutations. Interphase fluorescent in situ hybridization (FISH) technique revealed a 15-fold increase of NMYC signals to chromosome enumeration probe signals, confirming NMYC amplification. Following this, multiplex ligation-dependent probe amplification (MLPA) assay was also performed on the neuroblastoma tissue to check for segmental chromosomal anomalies on chromosomes 1, 2, 3, 4, 7, 9, 11, 12, and 17 [Table 1]. The parents were offered to undergo genetic testing to find out any genetic abnormalities, but they refused to undergo such tests.

While on cisplatin and doxorubicin regimen chemotherapy (drugs common for both hepatoblastoma and neuroblastoma), he presented with convulsions (probably hypoglycemic) and shock requiring inotropic support and cardiopulmonary resuscitation. He was then diagnosed to have severe chemoprot-site sepsis (culture positive), which had to be removed once stable. Post this incident, the child developed hypoxic brain injury with neurological deficits in the form of weakness and regression of milestone. He is now on the road to recovery. At the time of reporting this case, he was not on any chemotherapy and was undergoing limb physiotherapy.

Discussion

Primary multiple tumors are defined as malignancies with different histopathological origin in one person. Its increased incidence seen nowadays is owing to better diagnostic techniques and improved treatment methods.[4] Multiple malignancies are reported along with TP53 mutation

**Figure 2**: (a) Intraoperative picture of adrenocortical carcinoma, (b) intraoperative picture of hepatoblastoma, (c) intraoperative picture of neuroblastoma
and LFS. Two distinct histological types of malignancies predominate the TP53 mutation reports. The most commonly associated malignancies with germline TP53 mutations and LFS are the adrenocortical malignancies, soft-tissue sarcomas, brain tumors, and breast tumors.[6]

There are multiple criteria which have been laid down for the identification of LFS which are classic and Chompret.[6] For those who do not fit into the classic criteria, Birch and Eeles have laid down criteria for identifying Li-Fraumeni-like syndrome (LFL). There is another syndrome which is described in literature called hereditary neoplastic syndrome. This is also associated with multiple malignancies and characterized by earlier onset of tumors than their described age. However, these are associated with endocrine tumors.[7]

Our patient does not fit into the LFS or LFL with any of the criteria laid down even with the presence of a renal cell carcinoma in his father. This makes our case a unique one with germline TP53 mutation and three histologically different malignancies (one of them being adrenocortical carcinoma) not matching the criteria for LFS and having malignancies other than the ones usually reported with LFS or LFL. This is a novel mutation, but its clinical significance needs to be proven in future.

Considering this case as a novel case of synchronous malignancies, the age of presentation also makes this unique, as most commonly the multiple malignancy syndromes are seen in the second or third decade.[9] This makes our case a unique one as the three distinct histopathological malignancies are reported at the age of 11 months. Three other reports were found where the patients are aged 6, 8, and 10 months.[5,9,10]

There are multiple cases of neuroblastoma which are reported with TP53 gene mutation [Table 2]. There are six reported cases of TP53 mutation with adrenocortical cancer (ACC) and neuroblastoma. This case is seventh such report.

The reported mutation in TP53 gene in our present case is a missense mutation c. C530G, p. Pro177Arg (P177A) with allelic ID 468390. This germline mutation has been identified in scientific literature to be present within the DNA-binding domain of TP53 but has not been biochemically characterized, and, therefore, its effect on TP53 protein function is still unknown, although speculated to have a partially gain-of-function mutation.[13] According to the International Agency for Research on Cancer (IARC) TP53 database, there has been only one somatic TP53 P177A mutation identified in colorectal cancer and no germline TP53 P177A has been identified till August 2018. Totally, there are 498 gene variants identified with TP53 mutation in the IARC TP53 database.[14]

The clinical exome sequencing also identified a mutation in the MLH3 gene which was a missense mutation c. G2221T, pVal741Phe (V741P) which is associated with hereditary nonpolyposis colorectal cancer (HNPCC) type 7. This type of HNPCC is known to cause early-onset colorectal, endometrial, gastric, and breast cancers.[15] According to the Centre for Genomic Study and Genetics, Zhejiang University, there are a total of 54 gene variants which are described for MLH3 mutation and most of them are on exon 2, as in our case. According to the same genetic registry, there have been only two instances of reports with V741P mutation, which were seen in adult familial endometrial carcinoma and colorectal cancer.[16]

The neuroblastoma tissue which was subjected to check for NMYC amplification test by interphase FISH assay revealed a 15-fold increase in the NMYC signals. Further, MLPA assay was performed to identify segmental chromosomal anomalies, which revealed alterations as tabulated in Table 1.

This case is particularly unique due to presentation with three histologically malignant tumors at 11 months of age. It did not fit into the criteria laid down for LFS in the presence of TP53 mutation and ACC with neuroblastoma. The gene mutation variant found is a novel missense mutation which has never been reported in germline mutation, while only one case is reported that of a somatic mutation (with colorectal cancer).[14] The MLH3 gene mutation variant V741P has not been previously associated with any of the malignancies seen in this child.[16] This indirectly may point toward the child developing any other malignancy association with this genetic aberration later in his life.

The MLPA assay and NMYC amplification rendered the neuroblastoma as a high-risk tumor. The chemotherapy regimen for high-risk neuroblastoma with NMYC, DDX1, and 2p amplifications consists of high-dose chemotherapy, irradiation, followed by immunotherapy.[17] The treating doctors were pushed against the wall for deciding the therapy as radiotherapy or high-dose chemotherapy cannot be performed because of TP53 mutation as these patients are known to develop more malignancies when exposed to radiation or other cytotoxic drugs.

A management protocol for these patients with multiple malignancies cannot be formulated as these are one-off presentation and each such presentation must be dealt individually.

**Conclusion – Take-Home Message**

Multiple synchronous malignancies are a rare occurrence in children. Cytogenetics (karyotyping, FISH, and comparative genomic hybridization) and molecular cytogenetics (MLPA and restriction fragment length polymorphism) in these cases help identifying the known mutations, whereas molecular cytogenetic techniques (denaturing gradient gel electrophoresis, single-strand conformational polymorphism, and heteroduplex analysis) will identify the unknown mutations. Genetic mapping of parents and siblings is crucial to identify inherited mutations or de novo
mutations. Establishing a chemotherapy regimen and tailoring it for these patients requires a multidisciplinary approach. Follow-up of these children with an eye out for a possible malignancy is of utmost importance.

Consent
A written informed consent has been obtained from the parents of this patient for publication of this case report and accompanying images. A copy will be made available at request.

Declaration of patient consent
The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient’s parents have given consent for their child’s images and other clinical information to be reported in the journal. The patient’s parents understand that their child’s name and initial will not be published and due efforts will be made to conceal identity, but anonymity cannot be guaranteed.
