

Secretory Leukocyte Protease Inhibitor in Oral Potentially Malignant Disorders and Oral Squamous Cell Carcinoma

Abstract

Objectives: Secretory leukocyte protease inhibitor (SLPI) is a protein found in body fluids and implicated as a prognostic factor in many cancers. There is limited research regarding serum and salivary SLPI in oral potentially malignant disorders (OPMDs) and oral squamous cell carcinoma (OSCC). **Materials and Methods:** A total of 90 participants were included in the study; of which 30 formed the control group, 30 included participants with OPMD, and 30 included participants with OSCC. Serum and salivary levels of SLPI were estimated using enzyme-linked immunosorbent assay. **Results:** Serum levels of SLPI showed progressive increase in potentially malignant disorders and SCC patients when compared with controls, while salivary levels were increased in both OPMD and OSCC groups as compared to controls. However, the difference between groups was not statistically significant ($P < 0.05$). **Conclusion:** The above results suggest that increase in SLPI levels in the serum may have a role in indicating progression of OPMD to OSCC.

Keywords: Oral potentially malignant disorders, oral squamous cell carcinoma, saliva, Secretory leukocyte protease inhibitor, serum

Introduction

Oral cancer is the 15th most prevalent cancer worldwide with a 50% survival rate despite recent advances in surgery, chemotherapy and radiotherapy.^[1] More than 95% of oral cancers are squamous cell carcinomas (SCCs).^[2] The high incidence of oral cancer in India is attributed to the habits of tobacco chewing and smoking. These carcinogens interact with the oral mucosa to cause premalignant and malignant changes. Most malignancies of the oral cavity arise from preexisting premalignant lesions.^[1] With a view to prevention of oral potentially malignant disorders (OPMD) developing into oral SCCs (OSCCs), various studies have tried to identify biomarkers in the serum and saliva.

Secretory leukocyte protease inhibitor (SLPI) was first isolated from secretions of patients with chronic obstructive pulmonary disease and cystic fibrosis and was thereby considered a major anti elastase inhibitor. SLPI is produced by neutrophils, macrophages, beta-cells of

pancreatic islets, epithelial cells investing the renal tubules, acinar cells of parotid and submandibular glands, acinar cells of submucosal glands, and epithelial cells lining mucous membranes of respiratory and alimentary tracts. SLPI protects the tissues by inhibiting proteases such as cathepsin G, elastase, and trypsin from neutrophils; chymotrypsin; and trypsin from pancreatic acinar cells and chymase and tryptase from mast cells. The main action is inhibition of neutrophil elastase which protects epithelial surfaces from damage.^[3] Initially studied for its role in the prevention of HIV transmission in saliva, SLPI has recently been recognized as a potential diagnostic and prognostic marker in the head-and-neck cancer.^[4] It is found in most secretions of the body and mainly in saliva.^[5] Previous research on SLPI has used brush biopsy specimens in OPMD and OSCC.^[6] This report demonstrated a significant decrease in SLPI in participants with oral precancer and cancer with the levels decreasing progressively from oral precancer to cancer. A recent study has evaluated archived salivary samples of patients who went on to develop OSCC and found that high salivary SLPI in smokers

was associated with increased risk of the head-and-neck SCCs (HNSCC).^[5] However, studies which have evaluated serum and salivary SLPI in OPMD and OSCC are lacking.

The present study aims to evaluate the role of serum and salivary SLPI in progression of OPMD into OSCC.

Materials and Methods

A total of 90 participants reporting to the outpatient department of our institute were included in the study. They were divided into three groups of 30 participants each: Group I included participants diagnosed with OPMD, Group II included participants diagnosed with OSCC, and Group III formed the control group. Participants with any underlying systemic disease were excluded from the study. Institutional Ethics Committee Clearance and written informed consent were obtained from each study participant. Demographic data were acquired from the participants and were followed by an examination of the oral cavity. Venous blood was withdrawn from the antecubital vein and serum obtained. Whole saliva was collected by asking the participants to allow saliva to collect in the mouth and then spit into sterile containers every minute for 5 min. Saliva and serum were stored at -20° until analysis.

Serum and salivary SLPI was determined using ELISA (Hycult Laboratories, Netherlands). The results obtained were subjected to statistical analysis.

Statistical analysis

Kruskal–Wallis test was used to compare the three groups. Intergroup comparison was done using Mann–Whitney U-test. Correlation analysis was performed using Spearman’s correlation test.

Results

Of the 30 participants with OPMD (study Group 1), 26 were male and 4 were female. The third, fourth, and fifth decades all had equal number of cases. Oral submucous fibrosis (OSMF) was the most common lesion in this group followed by leukoplakia and erosive lichen planus [Figure 1]. Gutkha chewing was the most common etiologic agent in OSMF, while smoking was associated with leukoplakia. Study Group II (OSCC) consisted of 24 males and 6 females. Maximum cases were seen in the 7th decade followed by the 6th decade. The most common site was the buccal mucosa followed by the tongue and the alveolingival sulcus [Figure 2]. Betel-quid chewing (BLAT) was the most common associated etiological factor [Figure 3].

Serum Secretory leukocyte protease inhibitor

The mean level of SLPI in the control, OPMD, and OSCC groups were 26.90, 44.78, and 105.56 pg/ml, respectively. The difference between the groups was statistically nonsignificant [Figure 4].

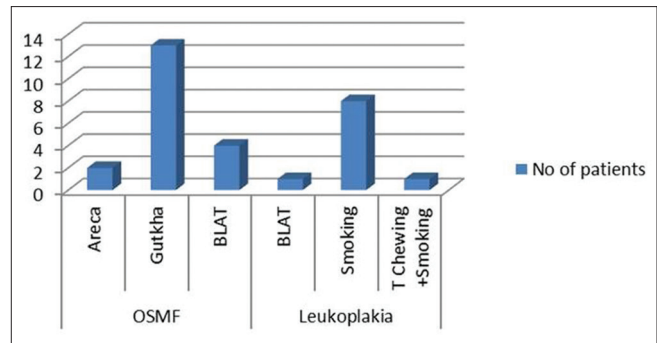

Figure 1: Graph showing the habits associated with oral potentially malignant disorders. Gutkha chewing was the most common etiologic agent in oral submucous fibrosis while smoking was associated with leukoplakia

Salivary Secretory leukocyte protease inhibitor

The mean level of SLPI in the control, OPMD, and OSCC groups were 80.28, 103.60, and 92.76 pg/ml, respectively. The difference between the groups was statistically nonsignificant [Figure 5].

Discussion

SLPI is an 11.7 kDa highly basic nonglycosylated protein. SLPI contributes to host mucosal defense of oral, nasopharyngeal, genital, and respiratory tissues. Salivary SLPI was initially studied for its anti-HIV activity.^[7] Studies have shown a protective function for SLPI against human papillomavirus (HPV) infection of the oral cavity.^[8] It has a major role in protecting tissues against the harmful effects of inflammation.^[3] It also has bactericidal and fungicidal properties.^[3] Even though the anti-HIV property of SLPI is well established, there appears to be no role for SLPI in other retroviral infections.^[3]

Recently, SLPI is being investigated for its role in a variety of cancers such as ovarian, breast, colorectal, pancreatic, and oral cancer.^[6,9-13] It has been implicated in cancer progression and metastasis.^[13] Cordes *et al.*^[14] demonstrated that lower SLPI was associated with metastatic HNSCC. Devoogdt *et al.*^[15] studied the role of SLPI in lung tumor progression and found that SLPI had definite promalignant activity. The authors concluded that this property of SLPI was due to its protease inhibiting activity rather than its property of increasing cell proliferation.^[15] Zhang *et al.*^[13] proved that elevated SLPI in pancreatic adenocarcinoma was associated with cell proliferation and growth of tumor.^[13] Decreased SLPI is believed to promote spread of the tumor by allowing degradation of tissues by proteases produced by tumor cells.^[8]

Quabius *et al.*^[16] found that decreased SLPI was associated with HPV-induced OSCC, while smoking-induced OSCC had higher levels of SLPI and absence of HPV positivity. Quabius *et al.*^[16] proposed that SLPI protects against HPV-induced OSCC in nonsmokers. SLPI increases in response to smoking and thus high levels are seen in smokers.^[8] Pierce Campbell *et al.* found that salivary SLPI levels were inversely correlated with age.^[17]

Figure 3: Graph showing the habits associated with oral squamous cell carcinoma. Betel-quin chewing was the most common associated etiological factor

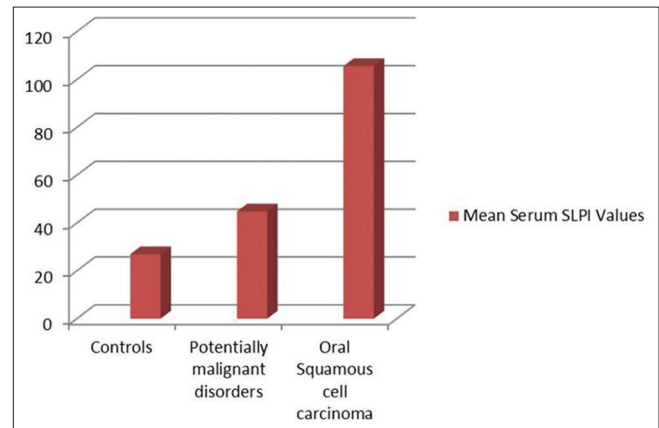

Figure 4: Progressive increase in mean levels of serum secretory leukocyte protease inhibitor in oral potentially malignant disorders and oral squamous cell carcinoma as compared to controls

The present study evaluated the serum and salivary SLPI in participants diagnosed with OPMD and OSCC to determine its role in the progression of precancer to cancer.

Male preponderance was seen in both OPMD and OSCC groups which is similar to previous literature reports.^[18,19]

OPMD were diagnosed from the third to fifth decade of life, whereas OSCC occurred predominantly in the 7th decade. This is in conformity with previous studies which have stated that OSCC occurs later due to accumulation of age-related mutagenic and epigenetic effects as also because most OSCC is believed to arise from pre-existing OPMD.^[20]

OPMDs are a group of oral conditions which include leukoplakia, erythroplakia, erosive lichen planus, and oral submucous fibrosis. The buccal mucosa was the most common site of OSCC in the present study. Previous studies conducted in India have reported similar

findings.^[20] Smoking was the etiological factor in most cases with leukoplakia, while gutkha chewing was associated with oral submucous fibrosis. Betel quid, a form of chewing tobacco which is composed of areca nut, lime, tobacco, and betel leaf, was the etiological agent in most cases of OSCC. According to the World Health Organization, 34% of the population uses beedis, 31% uses cigarettes, 19% uses smokeless tobacco, 9% uses hookah, and 7% use other types of tobacco, while the Cancer Patients Aid Association of India found that cigarettes accounted for 20%, beedis 40%, and chewable tobacco accounted for 40% of tobacco use in India.^[21]

A mass spectrometry-based quantitative shotgun proteomics study of oral brush biopsy specimens found that SLPI was progressively decreased in patients with OPMD and OSCC as compared to healthy controls.^[6] This decrease was correlated with the development of OPMD and OSCC. They further suggested that treatment with SLPI could have

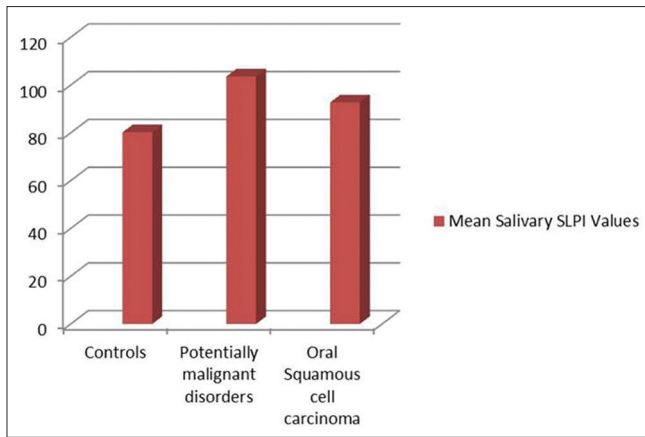

Figure 5: Increased mean levels of salivary secretory leukocyte protease inhibitor in oral potentially malignant disorders and oral squamous cell carcinoma as compared to controls

preventive effects.^[6] The present study compared the serum and salivary levels of SLPI in patients with OPMD, OSCC, and healthy controls.

The present study found that serum levels of SLPI increased progressively from controls to OPMD patients to OSCC patients. The difference between the groups was not statistically significant. We were unable to correlate these results with literature reports since previous studies on serum SLPI levels in OPMD and OSCC are not available.

Salivary levels were higher in OPMD and OSCC as compared to controls. However, the difference between the groups was not significant. Wen *et al.*^[22] found that SLPI was inversely correlated with tumor invasion in the head-and-neck OSCC and has implications for prognosis and treatment planning. However, in ovarian cancers, SLPI was found to be upregulated.^[11,22] Pierce Campbell *et al.*^[5] evaluated salivary SLPI and found that higher SLPI levels among smokers showed a higher risk for development of OSCC.

Decreased SLPI levels have been associated previously with a higher risk of tissue invasion. The present study showed higher levels of SLPI in OPMD and OSCC. These findings could probably be explained by the anti-inflammatory properties of SLPI which led to increased levels in saliva and serum. Although the results in the present study were not statistically significant, there was progressive increase in serum SLPI from controls to OPMD to OSCC indicating that serum SLPI could have a role in evaluating the progression of OPMD to OSCC.

The major limitation of the study is the sample size. Our study was more in the nature of a pilot study, and therefore, studies with larger sample size are required before definitive conclusions can be drawn.

Conclusion

SLPI is believed to have a role in tumor progression. It also has potential roles in prognosis and treatment planning

in OSCC. Studies on SLPI in different types of tumors have provided conflicting results. Salivary and serum levels of SLPI have not been evaluated so far. Our study aimed to determine the role of SLPI as a prognostic factor in the progression of OPMD to OSCC. The present study showed increase in serum SLPI in cases with OPMD and OSCC as compared to controls. Salivary levels of SLPI were also increased in OPMD and OSCC as compared to controls. Our results may reflect the anti-inflammatory properties of SLPI. These preliminary results appear to indicate that increasing levels of SLPI in the serum may indicate progression to OSCC. However, since the sample size of the present study was small, large-scale studies are required before any definitive results.
