Linear scleroderma, a subtype of localized scleroderma, is a rare disease that causes severe subcutaneous and deep tissue atrophy, which may result in a considerable psychological burden for patients [1].

Herein, we report the case of a 37-year-old female patient with linear scleroderma successfully treated with a superficial circumflex iliac artery perforator (SCIP) flap [2]. She had a linear brown plaque and marked atrophy of the skin and subcutaneous tissue of the left lower jaw that had lasted for 3 years (Fig. 1). The disease had been stable for more than 2 years. Preoperatively, the SCIP and superficial circumflex iliac vein (SCIV) were identified and marked with color Doppler ultrasonography. A 12×6 cm flap was designed, and an incision was made along the left inguinal ligament. Primary closure was performed at the donor site (Fig. 2). End-to-side and end-to-end anastomosis of the SCIP to the left facial artery and SCIV to the left facial vein, respectively, were performed. An adipose flap with only the monitoring flap was obtained by denuding. No relapse or complications were noted 3 months postoperatively (Fig. 3). Moreover, the concealed donor site was ideal

Clinical findings postoperatively. Three months after the operation, the contour of the patient's face was bilaterally symmetrical.

# various thicknesses [3].

For the complex reconstruction of facial tissue, a relatively noninvasive flap with a thickness that can be easily adjusted according to the location is ideal. The SCIP flap is likely to become an option for treating such cases.
